THE FUNCTION OF A TEACHING HOSPITAL*

61

ICS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD

relationship between teaching hospital and ersity is an old one In most cities the teaching ital is older than the university, and in some of them ably London) medical schools attached to hospitals dated the university and were later incorporated Yet most of these hospitals, at the time they were t, did not differ much from non teaching hospitals ther in structure, staffing or administration From we may deduce that, if they felt that their service to community differed from that of other hospitals, difference in function must have been very limited evidence received by the Royal Commission on the ersity of London (1913) leaves no doubt that it was act restricted to the acceptance of students as entices to learn the practical handling of the sick the physicians and surgeons to the hospital This is, and always must be an important function of hing hospitals for on it depends the practical ruction of general practitioners and specialists who the basis of any health service, organised or ganised And it was enough for the dark ages of icine, when familiarity with the natural history of ase, and with the lives of ordinary and extra ordinary made up the whole armamentarium of the practising or But it has become increasingly inadequate over last two centuries, because of the growth of natural ice

* * *

atural science, in essence, is a method by which the al sequence of events may be traced and identified an be, and is being, applied to the whole field of ral phenomena, beginning with the physical sciences, eeding to the biological sciences, then to the clinical ices, and more recently to the social sciences To scientist himself the purpose of science is to acquire ledge *for its own sake*, *to the community at large* usefulness of science depends on applying knowledge on, to the control of natural phenomena in the ests of man himself This distinction between the isition and the use of knowledge is to my mind the er distinction between pure and applied science ould seem self evident that knowledge must be ired before it can be used

appreciation of this is essential if the true function e teaching or university hospital is to be understood it is the function of the universities to acquire ledge, to impart that knowledge, and to teach the ods of acquiring it, and it is the function of the h service to use that knowledge in the prevention cure of disease The teaching or university hospital has a unique function in marrying these two points iew It alone can, should, and must provide the point for the acquisition of new knowledge concerning disease, for teaching how that knowledge can be and for pioneering the use of that knowledge in the ention and cure of disease To quote the words of William Osler, uttered half a century ago on the ect of the Johns Hopkins Hospital

> the type of school I have always felt the Hospital ld be and which we tried to make it—a place of refuge he sick poor of the city—a place where the best that is n is taught to a group of the best students—a place e new thought is materialized in research—a school where men are encouraged to base the art upon the science of medicine—a fountain to which teachers in every subject would come for inspiration—a place with a hearty welcome to every practitioner who seeks help—a consulting centre for the whole country in cases of obscurity We must convince the authorities that the subjects of clinical work come directly within the sphere of the university and that certain hospitals must be adapted to meet the demands of the scientific study of disease and the scientific training of students "

* * *

What does a university or teaching hospital need if it is to fulfil its central purpose? Its most important need is undoubtedly that its board of governors, administration, and staff should be united in recognition of their opportunity and in determination to realise it Secondly, it needs a medical staff skilled in the several disciplines which constitute the practice of medicine Some if not all, should also be skilled in scientific method, and able to devote a substantial part of their time to the acquisition of new knowledge and its application to the problems of the sick, and some should have such close *contact with other scientific* disciplines that they can use in their own work the methods and knowledge so gained It needs adequate inpatient and outpatient facilities for the treatment of the sick for the investigation of disease and for the teaching of students Finally it needs laboratories where those who are trying to advance knowledge may work, for the advances of technology have equipped us with techniques and machines that now enable us to get an answer to questions which have hitherto defied analysis

Judged by these standards, and indeed by contemporary practice as I have seen it in the United States, Canada Scandinavia, and Western Germany, most of our teaching hospitals in Britain are woefully inadequate The new building in Sheffield is a sign that we are moving in the right direction, but not all cities are as fortunate as is Sheffield I want to examine, therefore, some of the reasons that have impeded or are impeding progress

* * *

One of the obvious reasons is money This may be important in the future, but it was relatively unimportant in the past, had the will been there, the means could have been found Without any doubt the most important reason has been the prevalence of two opinions (1) that the advancement of clinical science is incompatible with the treatment of the sick, and (2) that all advances in medical science come from the preclinical laboratories, and that the clinical sciences are unnecessary to the advancement of medicine Neither of these opinions are rational and like most irrational opinions they are based on mistrust and fear The first has been held by the less enlightened consultant physicians and surgeons who fear that university departments menace the prestige which was once their monopoly in clinical subjects The other has been held by non clinical scientists who fear that the growth of clinical science will compete for the support available for scientific research I have no doubt that these attitudes of mind are being overcome, and they are being overcome in the only possible way, by the growth of mutual respect between colleagues with a common purpose—the relief of human suffering

But although these attitudes of mind, are dying they are by no means dead, and I know of nothing so mischievous to our common purpose Three examples will perhaps illustrate why I feel so strongly on this subject

When I was a student I was vividly impressed by the tragedy of two patients—a wood-worker who had driven a nail into his hand two days before he came to hospital with a grossly inflamed hand, and who died the next day of septicæmia, and a nurse whom I helped to hang the Christmas decorations and who died three days later

---

m an address given on the occasion of the opening of the w university building at the Sheffield Royal Infirmary

17

of a cavernous sinus thrombosis following a boil on her lip Their deaths were not attributable to any lack of skill or attention but solely to lack of knowledge They would not have occurred today thanks to penicillin, discovered and developed by Fleming, Florey, and Chain, working severally in the laboratories of St Mary's Hospital and Oxford University

Again when I was a student, patients with pernicious anæmia invariably died Today they do not die, thanks to the discovery by Minot and Murphy, working in the Thorndike laboratories of the Boston City Hospital, of the efficacy of liver, whose active substance has recently been identified and characterised by brilliant work of chemists and physicists

Finally, one of the commonest disabilities of middle-aged women in my student days was iron-deficiency anæmia This was then invariably and quite unsuccessfully treated with a mixture containing 7 grams of iron and ammonium citrate and 2 minims of liquor arsenicalis, a preparation which was demonstrably inactive It was only later, thanks to clinical experimentation, that it was found that much larger doses of iron were needed, and nowadays such are among the most grateful of our patients

These examples show that good doctoring and good nursing are not enough Knowledge, too, is needed, and knowledge is most easily and certainly won by the scientific method And while history shows abundantly that the key information may come from any discipline—from departments of medicine, surgery, pathology, physiology, pharmacology, biochemistry, and even the so-called basic sciences—knowledge tends to advance over a broad front, and it will not advance if the important disciplines concerning disease in man are neglected Thus the services of the teaching hospital are not only services to the individual patients, they are services to humanity as a whole

Although professional jealousy is the greatest hindrance to the development of the teaching hospital, an important misconception plays a part It relates to experiment To some minds experiment in medicine has come to mean something immoral or unethical which is inflicted on the individual patient against his own interests This is not so May I remind you of the nature of an experiment It is the alteration of preferably, one, or sometimes more than one, factor, and the observation of its effect All treatment is in fact in the nature of an experiment If we take a sick patient and we alter his diet, or his way of life, or give him a drug, or perform a surgical operation, we are, in the scientific sense, performing an experiment Most doctors, however, are not interested in the result, or have not sufficient time to assess the results properly It is the peculiar function of university departments of medicine, surgery, obstetrics, and therapeutics that they shall have the scientific training so to devise their treatment, and that they shall have enough leisure so to observe and assess its results, that new knowledge shall result Thus will their patients reap greater benefits and all mankind shall profit

Let us, for example, contrast the knowledge gained about the efficacy of the new antituberculous drugs with that gained about sympathectomy in hypertension By means of careful design and observation, it became abundantly clear, from the first patients treated in this country, how far and in what conditions streptomycin, p aminosalicylic acid, and isoniazid would help patients with pulmonary tuberculosis As a result the sick of the country as a whole got the maximum benefit from these drugs as soon as possible Not a single life or a single day of illness was unavoidably wasted Contrast sympathectomy for hypertension, an operation performed on thousands of patients, but without plan, so that now, some twenty years after its introduction, we still do not know how much it increases expectation of life in any but the most severe forms of hypertension is contrast between the results of a well planned and a badly planned experiment provides one of the eloquent pleas for the place of the university medicine

* * *

One final word The success or failure of the service of the future depends on its esprit de The spirit of the health service depends more spirit of our teaching hospitals than on any other the teaching hospitals set the standard and they the men Now it seems to me very important we are to get the best out of our teaching hc we should spare no effort to recruit the best men, to permanent staff No man who has had a long as I have, in staff recruitment can be happy wi present system in which men are appointed to posts for life, and the filling of staff vacancies at t hospitals depends too largely on the accidents of and deaths The Scandinavian system, in which move from smaller to larger hospitals and teaching hospitals seems to me better In the first it gives the teaching hospitals an opportunity of the best, for these men have proved themselves in field Secondly it provides an incentive to excel, for general excellence is rewarded Finally, I doubt if good for most men to remain in precisely the same for thirty five years, particularly when the unc of private practice has been removed This is not a point of outstanding importance, but e in a service demands attention to such details

CAROTICO-VERTEBRAL STENOSIS

M B Manc
LECTURER IN NEUROPATHOLOGY IN THE UNIVERSITY
MANCHESTER

The recognition of the frequency and sig of occlusion of the cervical portion of the carotid has been a major advance in the study of ce vascular disease Atheroma in this site has been forward as a reasonable pathological explanation the many cases of cerebral infarction which have known to occur without occlusion of the intra vessels Indeed, the clinical study of patients in the carotid artery has been occluded in the neck led to the recognition of various clinical syndr which are described in full in the writings of (1951, 1954), Cloake (1951), Symonds (1955), and others

Our personal experience, like that of others, has that occlusion of the carotid artery may be present out symptoms, signs, or infarction of the brain, it may be the basis of a clinical picture identical every way with thrombosis of the middle artery, and, finally, that it may be present when clinical picture is one of a steadily progressive cranial lesion presenting perhaps with dementia, mittent sensory and motor phenomena, or visual turbance—a picture often indistinguishable from caused by a cerebral tumour

It is difficult, however, to accept that such a clinical spectrum should depend solely on of one or even both carotid arteries For this rea seemed logical to investigate the major col channels—the vertebral arteries and the circle of W in cases of carotid-artery occlusion in an effort to an explanation for some of the discrepancies between clinical and the pathological pictures

We have previously reported (Hutchinson and Yates 1956) the results of an investigation into the incidence of atheroma of the vertebral artery in its cervical portion a segment of the artery rarely examined routinely at necropsy. We found that stenosis and occlusion due to atheroma in this part of the vertebral artery might be responsible for a characteristic pattern of infarction of the cerebrum and cerebellum. It seemed also that these changes in the vertebral artery, often accompanying atheroma of the carotid artery, might play an integral rôle in certain of the syndromes previously attributed to occlusion of the carotid artery alone.

Further study has confirmed us in this view. Indeed the association of vertebral and carotid atheroma is so common that we suggest that the term "caroticovertebral stenosis" gives the correct emphasis to the part played in disease by atheroma of the four major arteries in the neck which supply the brain (the internal carotid and vertebral arteries) and to the site of the vascular lesion in many cases of cerebral infarction.

Another aspect of vertebral-artery stenosis and one of some importance is that such stenosis alone may be responsible for infarction of the brain without either occlusion of the intracranial vessels or disease of the carotid arteries. We present here observations on these aspects of cerebrovascular disease.

Technique

To examine the cerebrovascular tree thoroughly, the brain was injected at necropsy with radio-opaque gelatin through the carotid and vertebral arteries at a pressure approximating to the systolic blood-pressure during life. The brain was then removed in the routine manner and fixed in formalin. In the first 38 patients in the series the vertebral artery was then dissected from the vertebral canal, but we found this method too laborious and time consuming for routine use; at the last 35 necropsies the cervical spine was removed with the carotid and the vertebral arteries in situ. Later the carotid artery was examined, the spinal cord removed from the cervical vertebræ, and the spine decalcified in 6% nitric acid. The vertebral artery could then be dissected from the vertebral canal with ease and examined at all points in its course.

* Extension of thrombus from internal carotid artery.

On the right a cross section depicting the degree of stenosis or occlusion at the worst point of the four major vessels in each case given. All the vessels are represented as of the same diameter except where striking and significant discrepancy was found.

Review of Pathological and Clinical Material

The observations presented are based on the study of 33 patients who came to necropsy as a result of a cerebrovascular lesion or whose clinical history suggested such an event in the past

Significant stenosis of the lumen of carotid and of vertebral arteries was often found, by "significant" we mean diminution of the lumen by at least half In 40 of the cases examined there was either significant stenosis or occlusion of one or more of the major vessels in the neck Of these, 10 had lesions of the carotid artery alone, and 7 of the vertebral artery alone, in 23 cases (more than half the total) the lesions involved both the carotid and the vertebral arteries

The pathological basis for the stenosis was always atheroma, with the occasional addition of either old or recent thrombosis A not uncommon finding was hæmorrhage into the base of the plaques of atheroma Although some of these hæmorrhages were small, others, by dissecting the base of the plaque, had obviously caused further sudden narrowing of the lumen of the artery Atheroma was particularly common at the origin of the vertebral artery from the subclavian artery and often extended up the vessel for some distance, otherwise there was no typical site for the atheroma in the course of the artery through the vertebral canal Atheroma was least common in the short intracranial segment of the artery, it was not unusual to find severe atheroma of the cervical portion of the vertebral and carotid arteries when the intracranial vessels were either free from disease or showed only minimal changes The carotid artery was often affected by atheroma just at or above the cervical bifurcation, the atheroma extending for a short distance up the artery Often the artery was free from atheroma above this site The details of the distribution of the pathological change in the carotid artery were similar to those reported by Samuel (1956)

In our series there were 22 cases of cerebral infarction (see table) Many had more than one infarct The total number of separate infarcts in the 22 cases was 47, of these, 29 were cerebral, 15 cerebellar, and 3 in the brain-stem In 16 of the 22 cases infarction was present without occlusion of an appropriate intracerebral vessel In 10 the following intracerebral vessels were occluded the anterior cerebral (2), middle cerebral (8), posterior cerebral (2), basilor (1), and posterior inferior cerebellar (1) In 3 cases the intracerebral occlusion was caused by extension of thrombus from the internal carotid artery We wish to draw attention to the frequency of multiple infarctions not only in the cerebrum but also in the cerebellum, and to the fact that in only 1 of the 15 cerebellar infarcts was the cerebellar artery supplying the infarcted area occluded

Finally, the spinal cord was examined in 35 cases, and in none was there either macroscopical or microscopical evidence of infarction

Since we are concerned to show what we believe to be the effects on the brain of either occlusion or stenosis of one or more vessels in the neck, we have grouped the material as follows (1) disease of the vertebral artery alone, (2) disease of the carotid artery alone, and (3) disease of both the carotid and the vertebral arteries —"carotico-vertebral stenosis"

(1) *Disease of Vertebral Artery*

In 7 patients the atheroma was confined to the cervical portion of the vertebral artery In 2 of these patients stenosis was the cause of infarction of the brain In both cases the infarction was confined to the territory ultimately dependent on the vertebral artery the brain-stem, the cerebellum, and the occipital lobe

Case 18 —A man, aged 47, had been in excellent health until, four months before death, he first complained of tingling in his right arm and right leg The tingling occurred in short

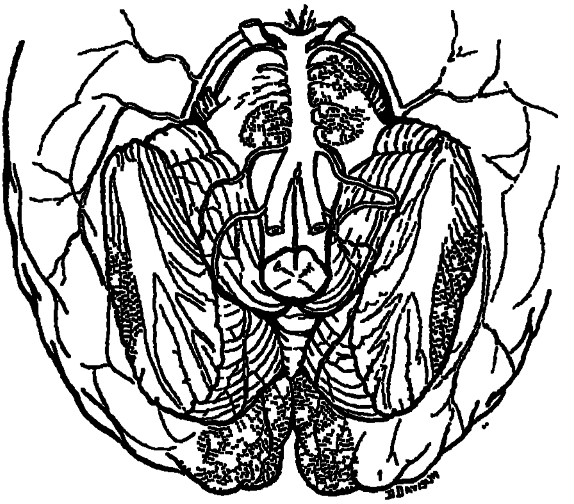

Fig 1—Case 18 distribution of infarcts

attacks, lasting a few minutes only, and was appreciat along the whole of the arm and the leg On occasion attacks were accompanied by a feeling of heaviness in t affected limbs, but the duration was so short that there no real disability, and he continued at his work Six day before death he suddenly became ill and complained persistent heaviness and weakness of both legs Next da he was very unsteady in walking From this time onwa he had difficulty in reading print On the evening of the second day a sudden attack of "jumping" of the right arm and right leg lasted for five minutes and was followed next morning by a similar attack in the left limbs Unlike the attack of -the night before, this attack was followed by persistent weakness From this time onwards the patient's relations noted a steady deterioration in his condition, with increasing weakness of all his limbs

On admission the patient lay quietly in the bed unable to move his head or his limbs and unable to speak or to swallow That he was fully conscious was shown by the fact that he moved his eyes fully in all directions in response to verbal requests His jaw, tongue, and palate were almost completely immobile His limbs were flaccid and powerless; his reflexes were not unduly brisk, his abdominal reflexes were absent and his plantar responses extensor Sensation was difficult to assess with any degree of accuracy, but it could be shown that pain sense was absent below his clavicles No useful information was obtained on his fields of vision The signs and their anatomical implication indicated thrombosis of the vertebral and basilar arteries The patient passed quietly into coma and died on the sixth day of the terminal illness Tracheotomy only temporarily relieved his respiratory distress

Necropsy Findings

The body was that of a well-nourished man of middle age The tracheotomy wound appeared healthy, though the trachea and main bronchi were acutely inflamed Both lungs showed active bronchopneumonia The coronary arteries were somewhat atheromatous but nowhere severely stenosed All the other organs of the body were essentially normal

The carotid arteries were normal throughout their course The intracranial vessels were normal except the left vertebral artery which had a plaque of atheroma, about 1 cm from its penetration of the dura, narrowing the lumen by a third The posterior communicating arteries were patent and of normal size The right vertebral artery was twice the size of the left It was occluded by organised thrombus extending from its point of entry into the vertebral canal opposite the sixth cervical vertebra to the level of the atlas

The brain (fig 1) showed bilateral infarction of the occipital lobes On the right side a single and fairly recent infarct extended from the calcarine region to the inferior surface of the lobe and to the posterior hippocampal fusiform, and inferior temporal gyri There were two distinct infarcts on the left side, one (a few weeks old) involved much of the cuneate gyrus, and the other was fairly recent and lay at the occipital pole in the lingual gyrus There was bilateral recent infarction of the cerebellum Both infarcts involved cerebellar foliæ rather than deep white matter and occupied an area about 2 cm in diameter in the centre of the upper surface of each hemisphere In the brain stem recent infarction involved the caudal half of the pons It did not involve the region beneath the floor of the fourth ventricle and was most extensive on the left side The cervical portion of the spinal cord was normal

Case 8 —A man aged 82 was admitted to hospital after a car accident Two months earlier he had fractured his right humerus but apart from this he was well until the recent accident He had been unconscious for only a few moments at the time of the accident and on admission to hospital the only physical sign of injury was a shallow abrasion of the skin over the right occiput Radiography of the skull however, showed a linear fracture of the left temporo parietal region The patient remained well for the next seventeen days and then suddenly complained of pain in the chest and intense dyspnœa Bronchopneumonia was diagnosed, but there was no response to treatment and he died suddenly three days later Unfortunately a detailed neurological examination was not made before he died

Necropsy Findings

The body was that of a poorly nourished old man showing no bruising or other evidence of trauma A linear fracture of the skull extended from the occiput to the right temporal bone, but the underlying dura was not torn Apart from terminal bronchopneumonia the organs of the body were not significantly abnormal There was no evidence of cardiac infarction

The right internal carotid artery was slightly narrowed by a plaque of atheroma just above its sinus, the left was normal The right vertebral artery was occluded at its origin from the subclavian artery, the smaller left vertebral artery was patent The intracranial cerebral arteries were all free from atheroma The posterior communicating arteries were patent but very small

The brain showed bilateral atrophy of the frontal gyri with thickening of the overlying arachnoid There were small recent petechial hæmorrhages in the arachnoid at the junction of the territories of the left middle and posterior cerebral arteries, typical of those seen at the borders of infarcted territory There was recent infarction of the medial and inferior parts of the right occipital lobe, there was an infarct of similar age in the right cerebellar hemisphere in the territories of both the anterior and the posterior inferior cerebellar arteries

In both case 18 and case 8 there was a considerable discrepancy in size between the vertebral arteries (a common anatomical variation), in both cases the larger artery was occluded by disease In case 18 the smaller left vertebral artery was partially stenosed by atheroma, and in case 8 the posterior communicating arteries were small and presumably incapable of sustaining a collateral circulation In both cases the terminal infarction appears to have come on spontaneously, the head injury in case 8 did not appear to have produced any significant cerebral trauma and could not be held responsible for the final fatal episode

(2) *Disease of Carotid Artery*

In 10 of our series the carotid was the site of either stenosis or occlusion without affecting the vertebral arteries at any point in their course In only 2 (cases 1 and 16) was infarction of the brain present That the vertebral arteries can maintain a precarious cerebral circulation in some patients is shown by the following example of long standing bilateral occlusion of the internal carotid arteries

Case 16 —A woman, aged 69, was admitted to hospital having been found unconscious in a gas filled room The only previous history of cerebral disease was that, for several weeks past, the patient had been noted by her relations to be rather forgetful When she recovered from coma next day, left hemiplegia was present, which persisted until she died six weeks later Death followed bronchopneumonia and the effects of prolonged sepsis from extensive bedsores

Necropsy Findings

The body was that of a wasted old woman with extensive decubitus ulceration of the sacral region There were extensive old pericardial adhesions but the heart was normal The coronary arteries were atheromatous but nowhere occluded Both lungs were involved by active bronchopneumonia The kidneys were irregularly shrunken (80 and 90 g) and showed the changes of chronic pyelonephritis The left internal jugular vein was blocked by newly formed thrombus

The left internal carotid artery was occluded in the neck by old organised thrombus at a point just above the sinus, the remainder of the artery being free from atheroma and thrombosis The right carotid artery was almost occluded in its intracranial portion, a small channel less than 1 mm in diameter remaining The atheroma responsible for this narrowing extended into the right middle and anterior cerebral arteries, which were occluded by thrombus for about 1 cm The circle of Willis was normal, except the right posterior communicating artery whose lumen was considerably diminished by atheroma The cerebral arteries on the left side were normal The basilar and the vertebral arteries throughout their length were patent and free from atheroma

The left cerebral hemisphere was normal The right showed infarction of part of the frontal and parietal lobes of the lateral part of the head of the caudate nucleus, and of the anterior half of the corpus callosum These infarcts dated probably from the time of onset of hemiplegia six weeks before death The temporal and occipital lobes were normal There was infarction of cerebellar foliæ in the territory of the right superior cerebellar artery (fig 2) The brain stem was normal

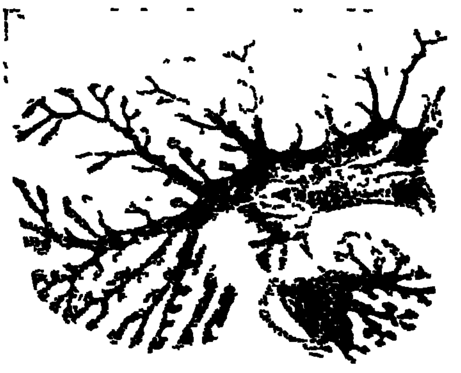

Fig 2—Case 16 section of cerebellum showing infarction of foliæ in territory of superior cerebellar artery

(3) *Disease of Carotid and Vertebral Arteries (Carotico-vertebral Stenosis)*

Atheroma of both the carotid and the vertebral arteries in the neck was present in 23 of the cases In 8 of them it is clear, from a study of the clinical history and the pathological material, that a combination of stenosis of both the carotid and the vertebral arteries was the vital factor in the production of the clinical picture For this reason we suggest the term "carotico vertebral stenosis," which emphasises to the full the underlying vascular disease

Both the clinical histories and the pathological examinations in these 8 patients allow of subdivision into two groups (1) 4 patients in whom the illness was sudden and fatal showed infarction of both the cerebral and the cerebellar hemispheres, and in 3 of the patients the infarction was precipitated by generalised circulatory failure, and (2) 4 patients had a clinical history of steadily progressive cerebral disease (3 of them required the aid of additional radiological techniques to exclude the diagnosis of a cerebral tumour, and in all 4 the findings in the carotid and the vertebral arteries were remarkably similar)

The findings in the first group of patients have been described in full elsewhere (Hutchinson and Yates 1956), therefore we repeat here only the essential clinical and pathological details These 4 patients (3 females and 1 male) all showed stenosis or occlusion of the carotid and the vertebral arteries in their cervical course In 1 of the patients the disease in the vertebral arteries was unilateral but had almost completely occluded the lumen of the right vertebral artery, which in this particular instance was nearly twice the size of the left—illustrating again the occasional importance that discrepancy in size between the two vertebral arteries may assume when disease develops. Three of the patients had no previous history whatever suggesting cerebral arteriosclerosis, and each died in coma developing in circumstances which led to circulatory failure. Stokes Adams attacks, carbon monoxide poisoning, and operative hypotension were the precipitating factors in the 3 cases. In the 4th patient symptoms due to intracranial infarction came on suddenly and apparently spontaneously. The necropsy findings in these 4 patients were identical in basic pattern. In each were found an infarct of one cerebral hemisphere and infarction (bilateral in 3 patients) of the cerebellum. The area infarcted in each case was either in or adjacent to the territory supplied by the superior cerebellar arteries in the cerebellum. In no case was the infarct associated with either occlusion or significant narrowing of the cerebellar or the basilar or the intracranial portion of the vertebral arteries. In all 4 cases the brain stem, though no doubt the site of terminal ischæmia, was free from frank infarction.

The 4 patients of the second group are considered together because their history was one of progressive cerebral disease. Though other patients in the series showed a comparable severity of stenosis in the vessels of the neck, the clinical history and opportunity for personal investigation were not adequate in these to allow of any detailed interpretation. The findings in 2 of the 4 patients were as follows.

Case 3.—A man, aged 70, complained throughout the summer of 1955, of constantly feeling tired and off colour. In September, 1955, his relations noted that he was a little forgetful, but the symptoms were so slight that they were put down to his advancing years. He remained in this state until April, 1956, when he was suddenly taken ill while on holiday. At this time he was confused and disoriented and showed distinct dysphasia. In addition to this there was an increase of the reflexes in the right arm and leg and a right lower facial weakness. Both plantar responses were extensor. He was admitted to hospital at this time.

On admission his cerebrospinal fluid (C.S.F.) was normal both in composition and pressure. Electroencephalography showed no evidence of a focal disturbance. Angiography of the left carotid artery revealed an occlusion just above the origin of the internal carotid artery. After this the clinical picture was most unusual. Although he was not apparently aware of his surroundings he constantly rotated to the left in bed, which movement persisted until his death six days later. Since it was still not certain that the underlying lesion was neither a subdural hæmatoma nor an infiltrating glioma, burr holes were made, and the underlying brain was seen to be infarcted.

Necropsy Findings

The body was that of an obese man. Apart from the brain and vessels in the neck there were no significant pathological changes. The aorta and coronary arteries were moderately atheromatous.

Of the cerebral vessels (fig. 3) the internal carotid arteries were both occluded by atheroma and thrombus. On the left side the lesion was old and organised; on the right it was recent. The left vertebral artery was narrowed to a thin slit for its first 2 cm. The lumen of the right vertebral artery was narrowed to half by an atheromatous plaque for 1 cm from its origin. Throughout the rest of their course these arteries were normal. The intracranial vessels (except the left middle cerebral artery, where there was a plaque 1.5 cm long which narrowed the lumen by half) were free from atheroma.

The left cerebral hemisphere was infarcted in two areas: (1) the posterior half of the middle and inferior frontal gyri involving the cortex and the gyral white matter; and (2) an area of 3 cm by 2 cm in the parietal lobe similarly involving cortex and gyral white matter. On the right side there were also two areas of infarction, but here both were in the parietal lobe, the more posterior extending to the junction of t parietal and the occipital lobes. The cerebellum and t brain stem were normal.

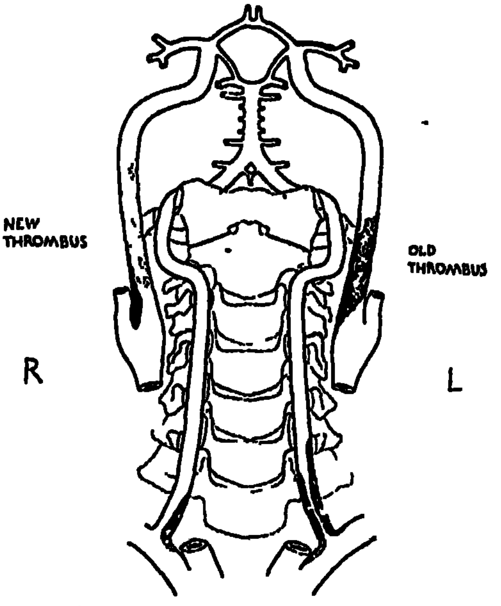

Fig 3—Case 3: sites of atheromatous stenosis and thrombotic occlusi

Case 10.—A man, aged 65, had been subject to twe months' progressive deterioration in memory and intellect power, as a result of which he had to retire from his job year before his retirement was due. From the onset of the symptoms his speech was slurred. Six months later developed symptoms due to prostatic obstruction but, becau of his mental state and severe old standing bronchitis, w not operated on. His dementia progressed over the ne six months, after which he was admitted to hospital f investigation.

On admission he had blood pressure 200/100 mm H prostate moderately enlarged, and blood urea level 120 m per 100 ml. He was confused and disoriented, and his spee was slurred. His reflexes were increased in all four limb and both plantar responses were extensor. Radiograph of his chest and skull and examination of his C.S.F. we normal. *He remained demented and died three weeks lat* from bronchopneumonia.

Necropsy Findings

The body was that of a thin emaciated old man. The hea weighed 350 g., the left ventricle being hypertrophied. Th coronary arteries were much stenosed by atheroma, but n myocardial infarction had taken place. Both kidneys we small (70 and 50 g.) owing to chronic pyelonephritis secondar to benign hypertrophy of the prostate. The other organ were not significantly abnormal.

The internal carotid arteries were severely atheromatou at their sinuses; both were narrowed by half at this point. Elsewhere in these vessels only slight atheroma was present. The right vertebral artery was occluded at a point 1 cm abov its origin; the left, which was the larger, was severel stenosed for the first 5 cm of its course. The intracrani vessels were free from disease.

The brain showed a small infarct at the posterior end of the left inferior frontal gyrus. The basal ganglia of both side contained several small old cysts, the result of earlier ischæmi An infarct, partly cystic, was found in the white matter of the right cerebellar hemisphere medial to and above the dentate nucleus. There was patchy necrosis of many cerebellar folia in the territory of the right superior cerebellar artery.

Discussion

Certain points arising from the pathology of these cases require consideration.

The common occurrence of infarction of the brain without occlusion of the intracranial vessels only confirms the observations of many previous workers. It is worth emphasising, however, that in no case of cerebral infarction in this series—where both the carotid and the vertebral arteries were examined throughout their length—was there any difficulty in providing a reasonable pathological interpretation for both the clinical phenomena and the distribution of infarction.

We were surprised by the frequency of infarcts in the hind-brain, particularly in the cerebellum. One reason for this finding was, we feel, the practice of fixing the brain in formalin before it was examined, thus making the softened areas of non-hæmorrhagic infarction easier to detect in the hardened brain.

In most of the cases we have described the infarct did not involve the "classical" sites such as the territory of the posterior inferior cerebellar artery. (Only 2 of 18 infarcts of the hind-brain were of this type: in both of these cases the vertebral artery was atheromatous throughout its cervical course.) The territory of the superior cerebellar artery near the point of junction with the territory of the posterior inferior cerebellar artery was the commonest site for these infarcts. Theoretically it is this area and the distal areas of the occipital lobes which may be expected to suffer if the vertebral circulation fails. These areas, in terms of distance from the source of supply, are the counterparts of the distal territory of the middle cerebral artery in which we found infarction when the carotid arteries were occluded in the neck.

Within the territory of the middle cerebral arteries we observed that the infarction was often incomplete and that areas of necrosis lay adjacent to areas of relatively normal tissue within the affected area. This patchy distribution of infarction where the site of the occlusion was proximal to the local vessel was no doubt an expression of the inadequacy, in the final stages, of the collateral blood supply.

Examination of the vertebral artery in its cervical course, by revealing either occlusion or stenosis, provided the pathological basis for those hind-brain infarcts which occurred without occlusion of the cerebellar vessels within the skull. In 4 of the cases the infarction was bilateral and approximately symmetrical within the cerebellum; in 3 others the infarct was unilateral. In addition infarction of the occipital lobes was present in 2 cases. In all these patients severe disease of the vertebral arteries in the neck was demonstrable, but in only 1 of them could the state of the cervical segment be deduced from the appearance of the intracranial portions of the artery. The midline structures—the pons, the medulla, and the spinal cord—escaped damage where the occlusions of the vertebral arteries were in the neck. It is a tribute to the efficiency of the circle of Willis as a collateral channel that it can maintain the blood-supply to the midline vital centres—in these circumstances an efficiency on which survival depends. In only 1 of these patients was the pons infarcted, and none of the 35 cervical cords was affected—surely surprising in the case of the cervical cord, where both vertebral arteries, the immediate source of supply in health, were often diseased or stenosed. No doubt the cord and brain stem were the site of ischæmia in the terminal stages in many cases.

The circle of Willis is not always adequate to maintain the blood supply to the hind-brain when the vertebral arteries are diseased. The necropsy findings in cases 18 and 8 show conclusively that the brain may become infarcted as a result of occlusion of the vertebral arteries when the carotid arteries and the circle of Willis are patent and healthy. The clinical history of case 18 is of considerable interest because the intermittent sensory and motor symptoms, spread over six months, were in many ways similar to the episodic history sometimes observed in patients thought to have occlusion of the carotid arteries. Very probably in this patient the site of production of the symptoms was either the brain-stem or the cervical cord. This may be the case in other patients where similar complaints have been attributed to occlusion of the carotid artery alone. Our material shows that many such patients have also stenosis or occlusion of the vertebral arteries in their cervical portions.

Atheroma affected the carotid arteries alone in 10 patients. In no case of unilateral involvement did cerebral infarction follow: in all the cases the vertebral arteries were patent. Moreover in case 16 at necropsy there was clear evidence of long-standing bilateral disease of the carotid arteries, and the only symptom noted by her relations before the terminal episode was occasional loss of memory. The final infarction was precipitated by accidental exposure to carbon monoxide. The pathological findings in this patient are of considerable interest. Despite the patent vertebral arteries there was infarction of the cerebellum in the territory of the superior cerebellar artery in addition to the infarct of the cerebrum. The posterior communicating artery on the same side was almost completely occluded by atheroma. The escape of the tegmentum and the cerebellum in cases of basilar thrombosis has been explained after the work of Critchley and Schuster (1933) and Biemond (1951) by the collateral circulation through the posterior communicating and the posterior cerebral arteries. The findings in case 16 not only support this explanation but also suggest that the territory of the superior cerebellar artery may partly depend on the carotid circulation even in health.

In our series the commonest condition of the major vessels of the neck was for all to be affected by atheroma, as we found in 23 cases. In 4 of the cases which were fully studied the clinical history was one of slowly progressive cerebral disease. Although in 2 patients there was a history of intermittent episodes no single feature of the clinical history pointed clearly to the diagnosis of vascular disease alone. In 3 patients it was necessary to resort to special radiographic techniques to establish the diagnosis. In the 4 cases the pathological findings were essentially the same—i.e., a severe stenosis caused by atheroma of all four major vessels in the neck. In contrast the intracranial vessels were in each case free from atheroma, although in 2 of the cases the final infarction of the cerebrum was associated with extension of the thrombus from the carotid artery into the middle cerebral artery.

Therefore we feel that this clinical picture should be regarded as an expression of progressive diminution of the total cerebral blood-flow owing to stenosis of the cervical portions of the major vessels to the brain. For this reason we suggest the term "carotico-vertebral stenosis" for these cases; to call them examples of internal-carotid occlusion places undue emphasis on the part played by occlusion of a single artery in the production of the symptoms.

A gradual diminution of the cerebral blood-flow alone cannot reasonably be held to explain the episodes of sensory and motor dysfunction which may be a feature of the clinical history. The common occurrence of small hæmorrhages in the walls of the carotid artery, within the plaques of atheroma, has already been noted (Yates 1954). We have suggested elsewhere (Hutchinson and Yates 1956) that the sudden development of one of these hæmorrhages in the coat of the artery may be a factor in initiating these transient episodes. Other factors—e.g., variations in the blood-pressure—may also play a part in disturbing the precarious balance of the already impaired cerebral blood-flow.

A sudden fall in the blood-pressure was almost certainly responsible for the development of terminal infarction in a further group of 4 cases. In 3 of them massive widespread infarction of the cerebrum and the cerebellum followed stenosis of the carotid and vertebral arteries associated with circulatory failure. Probably these patients, since they were free from any clinical sign of cerebrovascular disease, would later have presented a clinical picture of what we have designated "carotico-vertebral stenosis" They emphasise one of the dangers of hypotension in the aged

Finally, we feel that the recognition of the atheroma confined to the extracranial portions of the major vessels of the brain has more than a theoretical interest Since the intracranial vessels may well be normal or, at the most, the site of a minimal atheroma, surgical replacement of one or other of the vessels in the neck would be useful and logical That surgery may successfully accomplish this is shown by the case reported by Eastcott et al (1954) Such an advance offers hope that the early diagnosis of patients in this group may lead to progress in the treatment of the patient with "cerebral arteriosclerosis"

Summary

The cerebrovascular tree, including the whole length of the vertebral and carotid arteries, was examined in 83 patients considered to have died of cerebrovascular disease

In these arteries occlusion or severe atheromatous stenosis of the cervical segments was common

A clinical syndrome and a pattern of infarction are reported where the vertebral arteries alone were diseased

Stenosis of the cervical portion of the vertebral arteries plays an important part in the clinical picture previously attributed to occlusion of the internal carotid arteries The term "carotico-vertebral stenosis" is suggested as a more appropriate title for this syndrome

A surprising severity of disease of the extracranial, in contrast to the intracranial, cerebral arteries was noted in many patients The hope is expressed that, by the early clinical recognition of such cases, surgical replacement of diseased segments of the internal carotid arteries might, by improving the total blood-flow to the brain, prove useful

We wish to thank Prof A C P Campbell and Dr Fergus R Ferguson for their helpful criticism, Miss D Davison and Mr E G Smith for drawings of specimens, Mr W Beech, Miss R Davidson, and Mr G Lamb for technical assistance, and Mr R T Johnson and Dr G E Smyth for the clinical details of case 3

We have preached the sermon of simplicity so long that we have tended to ignore the fault into which we have been drawn of stripping the language clean to a degree that nothing shows, in spots, but the bones Case records are made to read like telegrams, and into the intercellular substance of our modern more or less technical writing, even as in the pronouncements of politics, where it matters less abbreviations trickle from the moving fountain pen like water dribbling from a leaky faucet It implies a degree of presumptuousness on the part of the author, an expectation that because a certain combination of initials means something to him it must mean the same to all The scientific culture of the day seems to be impelled by a sense of urgency in the delivery of its messages but one need scarcely recognize in it the urgency that must have inspired the abbreviations used by the hieroglyphic author of a former day trying to get a short article off to his editor by the afternoon bullock cart Verbosity is a fault but so is cryptogrammic abbreviation Midway lies clear and incisive language, confusing neither by the use of unnecessary words nor by the omission or mutilation of necessary ones"—Dr JOSEPH GARLAND, *Int Rec Med*

TREATMENT OF ACUTE SORE THRO WITH PENICILLIN

A CONTROLLED TRIAL IN YOUNG SOLDIERS

W BRUMFITT *
M B Lond, M R C P
LATE CAPTAIN R A M C

J D H. SLATER
B A, M B Camb, M R C P
LATE CAPTAIN R A M C

From the Cambridge Military Hospital and the So Command (Leishman) Laboratory, Aldershot, Hants

ACUTE sore throat is one of the most common plaints in medical practice today Although short it is important because serious disease such as rheumat fever or acute nephritis may follow streptococcal infections of the throat Under Service conditions in the United Kingdom cases of acute sore throat fever are usually admitted to hospital instead being treated in barracks Since, in civilian prac such patients are treated at home, a unique oppor arises in military hospitals for the study of t complaint

Exudative pharyngitis is often regarded as being caused by the hæmolytic streptococcus without bact logical confirmation and is consequently treated with penicillin, other antibiotics, or sulphonamides In many such cases, however, no streptococci are found by bacteriological examination (Commission on Acute Respiratory Diseases 1944), so there is no specific need for penicillin Furthermore there is the risk of inducing penicillin sensitivity, and the work of Brown (1948, 1956) indicates that this is not negligible

We have conducted a controlled therapeutic trial to see whether it is reasonable to exhibit penicillin routinely to all patients with acute pyrexial sore throat without previous bacteriological identification of the infecting organism We describe here the effect of four days' treatment with intramuscular penicillin on the clinical course and complications of acute sore throat, on the subsequent increase of streptococcal antibody in the serum, and on the convalescent carrier rate of β-hæmolytic streptococci

Material

Between March and May, 1955, and September and December, 1955, 352 patients with infection of the upper respiratory tract were admitted to the Cambridge Military Hospital, Aldershot This is the expected numb and indicates endemic disease Almost all of these patients were National Servicemen, aged 18–21, undergoing military training Our cases were derived from these according to the following clinical criteria

(1) The primary complaint was sore throat

(2) Pyrexia was present (100 3°F on any one occasion o 99 3°F on two or more occasions within twenty four hours)

(3) Admission was within seventy two hours of the onse of sore throat

(4) There was no clinical evidence of more generalise disease of which sore throat may only have been a coinciden feature (e g, glandular fever)

So that the investigation should be as uniform a possible, the clinical and pathological investigations were made entirely by us The patients' signs and symptoms were assessed clinically every morning on a special chart Each patient was asked whether or not his throat fel sore, and his answer was recorded The degree of rednes and the amount of tissue swelling seen in the throa

I—COMPARISON OF TREATMENT GROUPS AT START OF PENICILLIN THERAPY

—	Streptococcal		Non streptococcal	
	Non specific treatment (40 cases)	Penicillin treatment (42 cases)	Non specific treatment (19 cases)	Penicillin treatment (20 cases)
Mean duration of sore throat before admission (days)	1.5	1.3	2.2	1.6
Mean initial temperature (°F)	101.6	101.8	100.8	100.6
Mean initial white-cell count (per c mm)	14,100	14,000	13,170	11,100
Percentage of cases with exudate	79	79	60	[illegible]
Percentage of cases with tonsillectomy	7	13	21	10
Percentage of patients aged 17–21 yr	80	82	[illegible]	[illegible]

(abnormal injection) the presence or absence of faucial or pharyngeal exudate, and the size of the cervical lymph nodes were likewise recorded in a crudely quantitative way. These daily assessments continued until the patient was discharged from hospital. The oral temperature was recorded twice a day at standard times. A swab from fauces and pharynx was obtained under direct vision by one of us on each day that the patient was retained in hospital, except Sundays. The swabs were immediately inoculated on to two plain horse blood agar plates, one of which was incubated anaerobically. In addition the swab was inoculated on to a gentian violet blood agar plate and on to Hoyle's medium. The various bacterial colonies were assessed quantitatively after overnight culture. Total and differential white cell counts were made at noon on the first, third, and fifth days after admission.

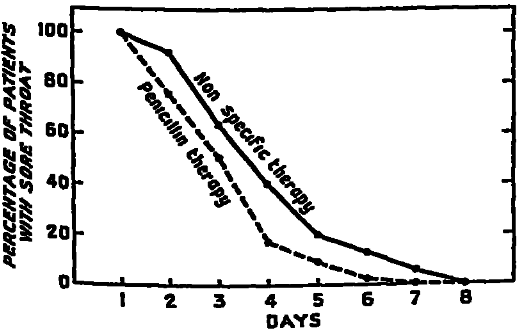

Fig 1—Effect of penicillin on duration of subjective soreness of throat in streptococcal cases

The patients were recalled three or four weeks after discharge, when they were questioned about recurrence of sore throat and about any symptoms suggesting either rheumatic fever or acute nephritis. A throat swab and a specimen of serum were obtained. Antistreptolysin O titres of the acute and convalescent sera were estimated in most cases by Dr R M Fry, of the Public Health Laboratory, Cambridge. A Paul Bunnell screening test was made on each specimen of serum. When Lancefield group A streptococci were recovered from the throat after three days' treatment with penicillin, the sensitivity of the organism to penicillin was tested.

Treatment.—A special ward was set aside for treating these patients only. Whether or not the patient received penicillin was governed by predetermined labelling of his allotted bed. The choice of bed for any particular patient was determined by administrative factors beyond our control, and the physician making the clinical assessments was usually unaware of the treatment. Patients receiving penicillin were given a combination of procaine penicillin 300,000 units and crystalline penicillin 100,000 units ('Seclopen' 1 ml) twice daily for four days, irrespective of clinical progress. Both groups received aspirin gargles at six hour intervals (mistura acidi acetylsalicylici *B P C* 1/2 fl oz). All the patients were treated in bed until their temperature had been normal for twenty-four hours.

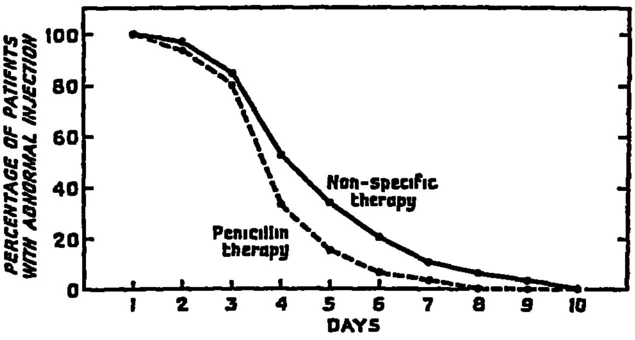

Fig 2—Effect of penicillin on duration of injection (œdema + redness) of throat in streptococcal cases

Results

121 consecutive patients satisfying the criteria described above were admitted to the trial.

For purposes of analysis they were divided retrospectively into two groups according to the bacterial flora of the throat.

(1) Those showing a predominant (60 cases) or a light (22 cases) growth of Lancefield group A streptococci on initial culture.

(2) Those from whom group-A streptococci were not isolated (39 cases). In 9 of these cases a light growth of hæmolytic streptococci not belonging to Lancefield group A was obtained, the remaining 30 showed a normal bacterial flora.

These two subdivisions will be referred to as the streptococcal and non-streptococcal groups, but we emphasise that the distinction depends entirely on whether or not group-A streptococci were isolated on initial culture. We do not mean to imply that streptococci were necessarily responsible for the illness.

Each of these groups was further subdivided according to whether or not penicillin was given, the division being

TABLE II—MEAN DURATION OF SPECIFIED CLINICAL FEATURES AFTER ADMISSION IN PATIENTS WITH AND WITHOUT LANCEFIELD GROUP-A STREPTOCOCCI IN THROAT

—	Streptococcal			Non streptococcal		
	Mean difference (days)	Standard error	Statistical significance	Mean difference (days)	Standard error	Statistical significance
Duration of sore throat	0.81	±0.32	Significant	0.42	±0.31	Not significant
Duration of pyrexia	0.95	±0.28	Highly significant	0.21	±0.43	Not significant
Duration of abnormal injection	0.98	±0.39	Significant	1.30	±0.66	Not significant

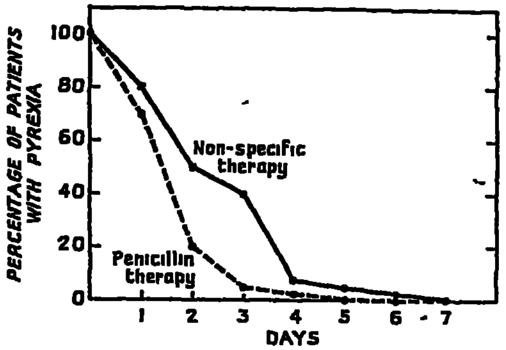

Fig 3—Effect of penicillin on duration of pyrexia in streptococcal cases

governed by random selection as described above In this way it was possible to assess the effect of penicillin in cases with and cases without a growth of group A streptococci on initial culture

Comparison of Treatment Groups—In table I specified clinical features are compared between the treatment groups It will be seen that the streptococcal cases on admission were reasonably uniform, whereas fairly large differences due to chance arose between the non streptococcal treatment groups

Duration of "Soreness" of Throat—The answers received in the streptococcal group are summarised in fig 1 The shorter duration of sore throat in those given penicillin is statistically significant, this is shown in table II The difference between the two treatment groups in the non streptococcal cases is not significant

Duration of Abnormal Injection of Throat—The results in the streptococcal group are given in fig 2, which shows that penicillin reduced the duration of abnormal injection of the throat in those harbouring streptococci The difference between the two treatment groups in the non-streptococcal cases is not significant (table II)

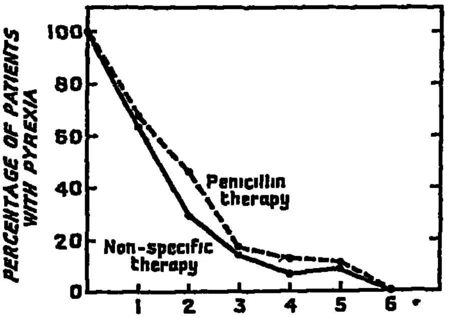

Fig 4—Effect of penicillin on duration of pyrexia in non streptococcal cases

Duration of Pyrexia—The results (figs 3 and 4) show quite clearly that penicillin reduces the duration of pyrexia by about twenty-four hours in those with group-A streptococci in the throat, whereas it has no effect in the absence of these organisms

Duration of Leucocytosis—Fig 5 shows the effect of penicillin on the duration of leucocytosis (11,000 or more white cells per c mm) in the streptococcal group It will be seen that 50% of those receiving only aspirin gargles still had abnormal counts on the third day, compared with 15% of those receiving penicillin Owing to the small numbers no definite statement can be made about the non streptococcal cases, but, at least, this gross difference on the third day was not seen

Antistreptolysin O Titre—The results are summarised in table III Surprisingly only 5 cases (16 7%) from the untreated streptococcal group showed a significant rise Only 1 case from the streptococcal group treated with penicillin showed a similar rise

Acute and Convalescent Carrier rate of Group A Streptococci—Fig 6 shows the proportion of patients from whom group A streptococci were isolated in hospital and during convalescence It will be seen that a four day course of intramuscular penicillin in adequate dosage did not eradicate the hæmolytic streptococcus from the throat in all the cases By the ninth day (four days after the end of penicillin therapy) 40% of the patients treated with penicillin produced group A streptococci, and during convalescence (three or four weeks later) there was no difference between the two treatment groups A penicillin sensitivity test was done in those cases showing a growth of the organism on the third day after admission and in no case were resistant strains of group A streptococci found

Complications Following Admission—There was one mild recurrence of sore throat after discharge from hospital among the streptococcal cases treated with penicillin No other complications developed after admission in any of the four groups, and there was no case of acute nephritis, acute rheumatism, or chorea

Discussion

Since the classical description by Felty and Hodges (1923) the syndrome of sore throat, pyrexia, faucial exudate, and painful lymphadenopathy is commonly regarded as being of streptococcal origin In practice, owing to the difficulties and delay in obtaining bacteriological confirmation of a diagnosis of streptococcal sore throat, many cases are treated with antibiotics or with sulphonamides on the basis of clinical diagnosis alone, but the possibility of accurately diagnosing streptococcal sore throat clinically has been disputed

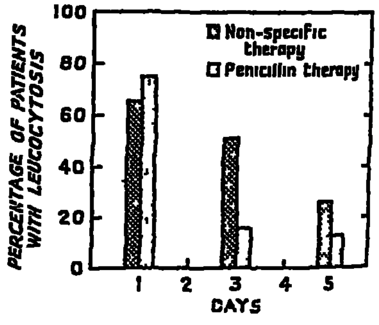

Fig 5—Effect of penicillin on duration of leucocytosis (11,000 or more white cells per c mm) in streptococcal cases

Rantz et al (1946) found that they could predict with an accuracy of 70% whether or not streptococci would be recovered from a throat swab, and the work of Breese and Disney (1954) supports this

On the other hand, in this country Landsman et al (1951) Bishop et al (1952), and Chapple et al (1956) could not separate streptococcal and non streptococcal varieties of acute sore throat

We too have found the diagnosis difficult, and, like the Commission on Acute Respiratory Diseases (1944, 1945, 1947), observed many cases of sore throat and pyrexia of abrupt onset with dysphagia and pharyngeal

TABLE III—EFFECT OF PENICILLIN ON INCREASE OF STREPTOCOCCAL ANTIBODY (ANTISTREPTOLYSIN O) AMONG STREPTOCOCCAL AND AMONG NON STREPTOCOCCAL CASES

	No of cases			
	Streptococcal		Non streptococcal	
	Non specific treatment	Penicillin treatment	Non specific treatment	Penicillin treatment
2 tube increase	5 (16 7%)	1 (3 3%)	1	0
1 tube increase	5	13	[illegible]	2
No increase or decrease	20	16	11	11

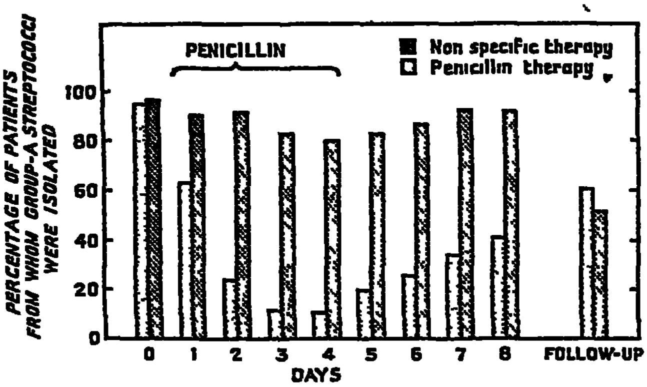

Fig 6—Effect of penicillin on proportion of patients from whom group-A streptococci were isolated on successive days after admission and at follow up three to four weeks later

exudate from which streptococci could not be isolated although repeated attempts were made to do so

Because of this difficulty in confidently diagnosing streptococcal sore throat without bacteriological aid we decided that it would be useful if all cases of acute sore throat satisfying our criteria (see above) were included in the trial In this way it is possible to compare the effect of penicillin therapy in those with and those without pathogenic streptococci in the throat

Intramuscular penicillin, rather than oral antibiotics and sulphonamides was chosen for assessment because (1) it is commonly used in practice for this complaint, and (2) it is generally regarded as the most efficient form of therapy for streptococcal sore throat (Denny et al 1953)

Streptococci were isolated from 82 (66%) of the 121 cases in the trial We must emphasise, however, that the so called streptococcal and non streptococcal groups are not ætiologically homogeneous, and that, even in those cases from which a predominant growth of group-A streptococci was isolated, the streptococcus could not be implicated with certainty as the cause of the initial illness (Commission on Acute Respiratory Diseases 1944, 1947) Nevertheless the results seem to justify this somewhat arbitrary and broad division into streptococcal and non streptococcal cases on the basis of bacteriological findings

The effect of penicillin on the symptoms and signs of the acute disease corresponds to the findings of Denny et al (1953), who were also studying young men, and of Bennike et al (1951), who investigated patients in all age-groups Like ours, both these series were treated in hospital

We find that the most striking effect of penicillin among those from whom hæmolytic streptococci were isolated was the reduction in duration of pyrexia and of leucocytosis (figs 3 and 5) This agrees with our clinical impression that the patients treated with penicillin felt better more quickly The duration of sore throat was also shortened, but, like the reduction in œdema and injection, the effect was not so great (figs 1 and 2) Owing to the small size of the sample no definite statement can be made about the non-streptococcal cases The fact, however, that there was no difference in the duration of pyrexia between the two non-streptococcal treatment groups suggests that penicillin therapy is unlikely to affect an acute sore throat unless streptococci are isolated

As regards the convalescent carrier-rate of group-A streptococci, our findings seem to differ from those of Denny et al (1953), who found a 10% convalescent carrier rate after a five-day course of intramuscular penicillin Their results refer to streptococci of the same type as those isolated during the acute illness Even lower figures were obtained by Bennike et al (1951) after a six day course of penicillin Our findings are based on a four-day course of penicillin, which was followed by a convalescent carrier-rate of group-A streptococci practically identical with that of the untreated group Wannamaker et al (1953) found that a ten day course of intramuscular penicillin was the only reliable way of eliminating streptococci from the throat

The real importance of acute sore throat is the risk of subsequent rheumatic fever or of acute nephritis Rammelkamp et al (1952), studying the effect of *epidemic* exudative tonsillitis in young airmen found that if typable group-A streptococci were isolated, the risk of subsequently developing rheumatic fever was about 3% Our experience, in this country, of more than 300 soldiers of a similar age with *endemic* exudative tonsillitis from whom group-A streptococci were grown, suggests that the risk of developing an initial attack of rheumatic fever is less than 1%, even in the absence of antibiotic treatment (unpublished)

Catanzaro et al (1954) have shown that rheumatic fever is not prevented unless the hæmolytic streptococcus is eradicated from the throat, whatever the increase of streptococcal antibody in the serum Therefore, if penicillin is being used as a prophylactic against rheumatic fever, a four-day course is of doubtful value

Therefore intramuscular penicillin will only be useful in cases of acute sore throat with pyrexia if hæmolytic streptococci are present A four day course will shorten the duration of symptoms by about twenty-four hours No other beneficial effect can be expected, and the risk of inducing drug sensitivity must be carefully considered

Summary

A controlled trial to assess the effect of a four-day course of intramuscular penicillin in acute sore throat with pyrexia is described

Penicillin reduced the duration of the illness by about twenty four hours only if Lancefield group A streptococci were isolated

Although penicillin suppressed a rise in antistreptolysin-O titre (which took place in a sixth of the cases not treated with penicillin), a four-day course of penicillin did not affect the convalescent carrier-rate of hæmolytic streptococci

We are indebted to Prof R Cruickshank for his constant advice and encouragement and to Colonel W R C Spicer and Lieutenant Colonel J A G Carmichael, whose interest and coöperation made the investigation possible Our results were analysed with the help of Mr D T Beeston, B SC, of the Army Medical Directorate (Statistics)

PAIN IN THE LOWER LIMB AFTER SYMPATHECTOMY

G D TRACY
M B Sydney, F R C S
CLINICAL RESEARCH ASSISTANT, SURGICAL PROFESSORIAL UNIT

F B COCKETT
M S Lond, F R C S
SURGEON

ST THOMAS'S HOSPITAL, LONDON

SINCE Royle (1924) described the technique of lumbar sympathectomy for spastic conditions, and made the incidental observation that the limbs became warm when deprived of their sympathetic supply, the operation has come to occupy an established place in the treatment of certain vascular disorders of the lower limb

Lumbar sympathectomy has been shown to have the following beneficial results

(1) Reduction of vasomotor tone, leading to increased blood-flow, especially to the skin and foot This may be effective in increasing the collateral circulation in obliterative arterial disease, in improving the skin nutrition in an ischæmic limb, so that ischæmic ulceration may heal, and in reducing the vasospastic component of certain peripheral vascular diseases (particularly those associated with Raynaud's phenomenon)

(2) A decrease in response to injurious environmental factors such as cold Thus the operation is effective in severe cryopathies—e g, conditions such as chronic pernio or erythrocyanosis frigida

(3) Elimination of sweating, especially of the foot In this way severe hyperhidrosis can be relieved

(4) Improvement in some patients with otherwise intractable causalgia There is no agreement as to how this result is produced

Certain complications have also been described (Ross 1935) These include troublesome dryness of the skin in the area affected by the operation, excessive sweating above it, and pain In this paper we describe the clinical features of the pain together with the results of studies made on a small series of cases, and discuss its possible cause

Investigation

The cases of post sympathectomy pain examined comprise those seen in the twelve months preceding May, 1956, in the surgical professorial unit of St Thomas's Hospital During that year 51 lumbar sympathectomies were carried out in 42 patients by members of the surgical unit Pain after operation was observed in 9 extremities (7 patients)

In each case the operation was performed through an anterolateral extraperitoneal incision and removal of the gangliohated trunk was confirmed by histological *section* The aim of the operation was to excise the paravertebral trunk from the sides of the second to the fourth lumbar vertebræ

Clinical Features of Post sympathectomy Pain

The clinical features were remarkably similar in each of the 7 patients The most constant feature was a *latent period* until the tenth to the seventeenth postoperative day, *when the pain appeared By this time the patients* had all been discharged from hospital The onset was sudden, the pain becoming severe and unremitting in some cases, and always worst at night In each case the pain had an identical *distribution to the anterior* parts of the thigh down to the knee, and corresponding quite closely to the distribution of the first and second lumbar dermatomes

The pain was associated with marked hyperæsthesia, and relief was not obtained with aspirin and codeine In 2 cases pethidine had to be given Some patients had sleepless nights for as long as three weeks, after which the pain usually began to abate

Physical examination revealed hyperæsthesia to light touch in the affected areas, with *cool, moist skin,* but with no sensory loss or other evidence of somatic nerve damage

Spontaneous remission occurred in all cases but 1 1 patient whose pain was very severe had relief over night after seventeen days With the others the pain subsided more gradually, taking from ten to sixteen weeks to disappear In 1 patient the pain is still present, though less severe, after five and a half months

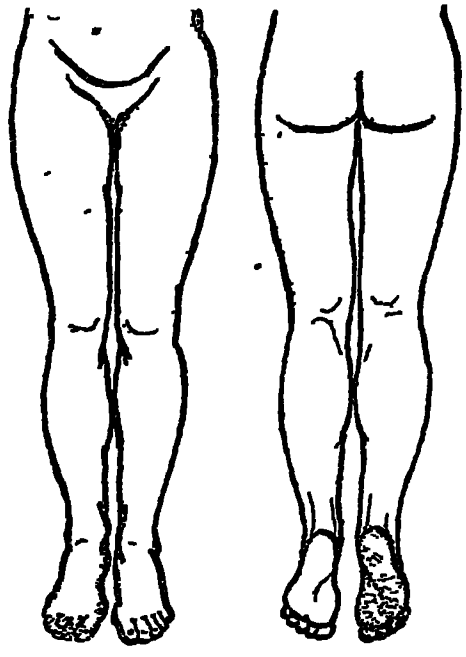

Fig 1—Skin-resistance pattern *after left lumbar sympathectomy* The darkest areas are those of lowest resistance (highest sudomotor activity)

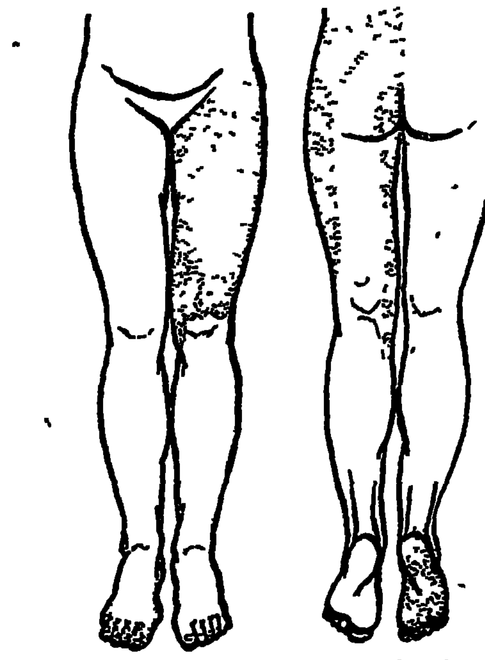

Fig 2—Skin-resistance pattern in a patient with post-sympathectomy pain Note the increased sudomotor activity over the area where the pain is felt.

SKIN RESISTANCE READINGS OVER THIGH

—	Thigh (Dermohmeter units)	Foot (in shaded area)
Normal	5–15 (10)	25–50 (40)
Lumbar sympathectomy (no pain)	5–25 (12)	0
Post sympathectomy pain	25–30 (30 approx)	0

This gives the range of values with the approximate average in each group in parentheses 1 of the 6 sensitivities was always selected to give a maximum deflection on the normal foot

Thus the duration of the pain may be summarised as follows

(1) Onset after a latent period of ten to seventeen days

(2) Spontaneous remission (occasionally with dramatic suddenness) after ten to sixteen weeks

Sudomotor Activity

The technique of measurement of the electrical resistance of the skin, developed by Richter (1947 et seq) was used to study these patients Richter and others have shown that the electrical resistance of the skin depends upon sweat gland activity and not on vasomotor or other physiological changes A puncture in the skin or an abrasion reduces the resistance almost to zero This test was selected as those which depend on bloodflow are subject to variable factors other than sympathetic activity, and cannot give information about the segmental distribution of sympathetic denervation

A small portable dermohmeter was used which is similar to the modification of Richter's apparatus described by Jasper and Robb (1945) It consists of a microammeter range 1 to 50 (with a deflecting needle to prevent overload) connected to nine 1½-volt batteries arranged in series, with a rotary switch providing six sensitivities The switch can be adjusted to obtain a large scale deflection of the meter in areas of normal sudomotor activity This was found to permit clear demarcation of the denervated zones without the use of a specially warmed environment to induce sweating

Skin-resistance measurements were carried out on all of the patients with post-sympathectomy pain except the first, and to establish a basis for comparison with these and other recorded patterns of skin resistance following sympathectomy, measurements were recorded from 19 normal limbs and from 16 limbs of patients who had undergone lumbar sympathectomy at times varying from several days to eleven years before, and who had not suffered the typical pain

Normal limbs —The pattern of skin resistance in the normal lower limb (figs 1 and 2, right leg) was found to be as described by Richter and others, with maximal readings (indicating lowest resistance) on the sole of the foot, especially the toes where sudomotor activity is greatest

Sympathectomised limbs without pain —The usual pattern following lumbar sympathectomy is shown in fig 1 (left leg) where the areas shaded darkest represent zones of greatest sudomotor activity In the unshaded areas this is zero In each case except 1 in which denervation appeared to be complete, sudomotor activity was found to persist in the anterior part of the thigh in the area coinciding with the first two lumbar dermatomes In 2 instances, readings slightly higher than those on the normal side suggest slight increase in sweating in this zone

The residual area of sudomotor activity following lumbar sympathectomy was noticed by Richter (1947) Ray and Console (1948) found the same residual-area in every one of a series of "total" sympathectomies, from the stellate ganglion to the sacral trunk They found that it was abolished after rhizotomy of the anterior roots of T12, L1 and L2, and described a technique combining this rhizotomy with lumbar ganglionectomy, which was said to produce complete sympathetic denervation without demonstrable motor weakness in the limb

A possible explanation for this phenomenon of residual sympathetic activity following lumbar sympathectomy has been provided by Kuntz (1950) who showed in anatomical dissections the presence of accessory ganglia in the anterior nerve roots of the upper lumbar segments, thus providing a pathway that by-passes the paravertebral trunk These accessory ganglia had previously been described by Wrete (1934) and Skoog (1947)

Sympathectomised limbs with pain —In the 8 limbs examined with post sympathectomy pain, *considerably increased sweating was discovered in the area of distribution of the pain*, compared to the normal side and compared to the sympathectomised but pain-free limb (fig 2) We could find no previous reference to this observation

Discussion

Post sympathectomy pain is a distinct entity—not to be confused with wound pain or with persistence of pain which was present before operation Although it is well known scant reference to it can be found in the English literature

Cohen (1953), referring to it as an "all too common complaint," describes as characteristic features the onset about the tenth postoperative day, worsening at night, with hyperæsthesia of the thigh and clearing within three to six weeks, "occasionally lasting months" Ross (1935) mentions it briefly, and Martin et al (1956) state that "the cause is not clear but it occurs in about 12% of cases"

Several possible reasons for this pain have been suggested (Simeone 1956) including

(1) Traction on the lumbar roots (Cohen)

(2) Degeneration of sympathetic nerve fibres causing root irritation

(3) Traumatic neuritis of the genito femoral nerve which lies close to the sympathetic trunk

(4) The presence of afferent fibres from the limb in the sympathetic trunk causing referred pain

None of these explanations seem adequate for the pain seen in our small group of patients The following factors appear to be significant

(1) The syndrome seems to be peculiar to the operation of sympathectomy, and is not seen after other operations in which somatic nerves may be injured

(2) The pain is constantly distributed to the front of the thigh in the first two lumbar dermatomes

(3) Residual sympathetic activity is always found in this area after a lumbar sympathectomy This is possibly due to the presence of accessory sympathetic ganglia, which occur even in cases without pain, in the anterior roots of L1 mainly but also in T12 and L2

(4) Greatly increased sympathetic activity in this area when it is the site of pain has been demonstrated in our observations

Other writers (Ross 1935, Grimson et al 1949) have referred to active sweating in other areas following sympathectomy, which may be an attempt to compensate for partial loss of sudomotor activity This is not always seen, and its relation to the increased sweating we have found in this small group with pain is a matter for conjecture

Summary

The clinical features of post-sympathectomy pain following lumbar sympathectomy are described

The results of studies carried out on 9 limbs with such pain following 51 lumbar sympathectomies are described

The new observation has been made that sudomotor activity is considerably increased over the area in the thigh where the pain is felt

We should like to acknowledge the interest and assistance of Prof J B Kinmonth and all the other members of the surgical unit at St Thomas's Hospital in this investigation

Congenital hyperthyroidism is rare, and all the reported cases have been the offspring of mothers who were thyrotoxic during pregnancy or had been treated for hyperthyroidism within a few years previously (White 1912, Margetts 1950, Fischer 1951, Jirsová and Brychnac 1953, Koerner 1954, Skelton and Gans 1955)

Juvenile hyperthyroidism is also uncommon Symptoms may date from the first few months of life and persist for many years (Ellis 1935) Koerner in 1954 was able to find only ten reports of hyperthyroidism in infants under 1 year of age, and McClintock et al (1956) had only one child below the age of 3 years in their own series Cattell (1949) found that, of all cases of Graves's disease, only about 1% occurred in children of 13 years or less

We report here a further case of true congenital hyperthyroidism, once again the offspring of a mother with thyroid disease

Case-report

The child's mother a woman of 25, had three normal children, the third being born in February, 1954 At the end of the same year she developed symptoms of hyperthyroidism—tiredness nervousness and irritability sweating, hunger, loss of weight prominence of her eyes and enlargement of her thyroid gland Partial thyroidectomy was performed in February, 1955 She apparently made a satisfactory recovery and for about 9 months, felt well without any of the symptoms which had previously troubled her

Her child a boy was born on Jan 19, 1956 The mother was 'only fairly well' during her pregnancy and felt that her eyes had again become prominent She became emotional and nervous but denied many of the symptoms of which she had previously complained

The infant was delivered at home by a midwife two weeks prematurely and weighed at birth 6 lb The midwife noted that the baby was limp and cyanosed and had bulging eyes He improved slowly, and about 6 hours later sucked vigorously when put to the breast Thereafter he was always hungry requiring 2 hourly feeding , but as the doctor did not wish the mother to breast-feed him, he was given 'Ostermilk no 1' It was estimated that in the second week of life he was receiving nearly 70 calories per lb of body-weight daily Despite this he did not sleep at night He was never jaundiced, but his mother noticed that his skin was very red and marked easily His bowels moved six to eight times daily, the motions being greenish On the day before admission his mother noted for the first time that he was easily startled and 'always moving" She also thought that his eyes were rather wide and staring He sweated freely His family doctor referred him to the Royal Hospital for Sick Children, Edinburgh on Feb 11 because of enlargement of his thyroid gland and failure to gain weight

Condition on Admission

The baby was very thin (weight 6 lb 1 oz) There was marked bilateral lid retraction and a suggestion of proptosis (figs 1 and 2) The skin was warm and moist, and dermatographia was easily demonstrated He was very alert and hyperactive, with increased muscle tone and an exaggerated response to noise and other stimuli He had a pulse rate of 176 His systolic blood pressure was 75 mm Hg (flush method) His thyroid was diffusely enlarged, but no vascular bruit was heard on auscultation over the gland Systematic examination was otherwise negative , in particular there was no cardiac murmur—or any evidence of jaundice, splenomegaly, or hepatomegaly

Investigations

Hæmoglobin 13·3 g per 100 ml White cells 13,500 per c.mm Urine normal Radiographs of chest and skull within normal limits *Radiographs of wrists showed epiphyseal* centres consistent with the baby's stated age Tryptic activity was present in the stools Electrocardiography revealed sinus tachycardia The serum bilirubin level was 0·8 mg per 100 ml , and the serum-cholesterol 140 mg per 100 ml The glucose tolerance curve was flat, the maximum rise being only 15 mg per 100 ml

A radioactive iodine test of the child's thyroid function was performed, using a dose of 1·6 µC of ^{131}I Urine was collected, through Paul's tubing attached to the penis, for 48 hours without loss In the first 24 hours 12·5% of the administered dose was excreted, and 1·2% was excreted in the 24–48 hour *period The uptake of iodine* by the thyroid gland appeared, by direct measurement to be about 90% of the dose after 24 hours

Treatment and progress—The baby was fed 3 hourly but remained hyperactive and extremely hungry He continued *to receive about 70 calories per lb* of body weight daily His

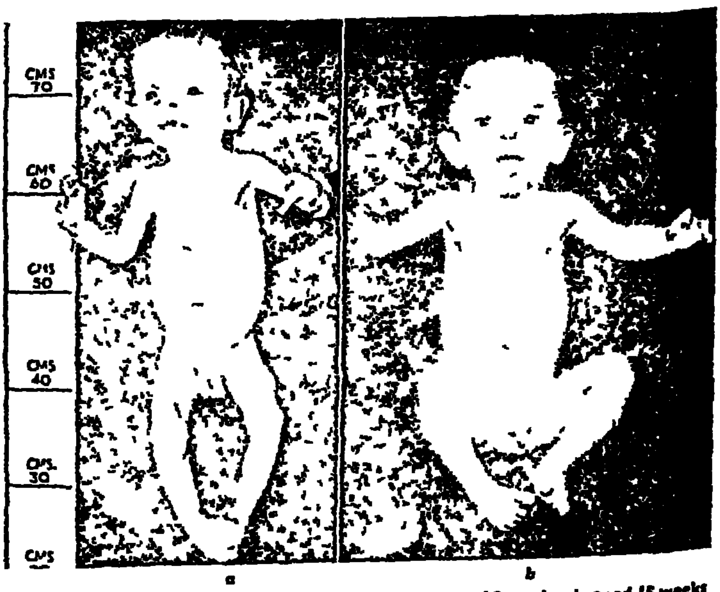

Fig 1—Infant with congenital hyperthyroidism *a*, aged 3 weeks , *b*, aged 15 weeks

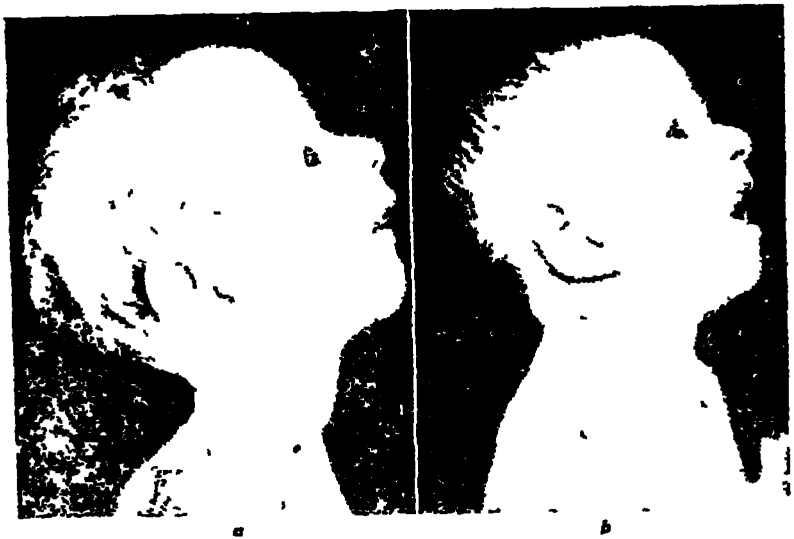

Fig. 2.—Same baby as in fig. 1. a, aged 3 weeks, with goitre and congenital hyperthyroidism. b, aged 15 weeks without goitre.

stools were loose, green, and very frequent, and in his first week in hospital his weight did not increase.

Treatment was begun on Feb. 17 with carbimazole 5 mg. and potassium iodide 30 mg. daily, and in 10 days he gained 1 lb. in weight. The administration of iodine was then stopped but that of carbimazole was continued in a dosage of 1.25 mg. daily until April 3. This quantity was then given on alternate days until April 17, when all treatment was stopped. As a result of treatment he became less restless and hyperkinetic, his pulse rate settled to about 126–134, and he produced one or two formed yellow stools daily. He was discharged from hospital on Feb. 28, weighing 7 lb. 10 oz., a gain of 1 lb. 9 oz. since the start of treatment.

His immediate progress thereafter was not entirely satisfactory, partly owing to maternal incompetence. He required readmission to hospital on March 6 for a week because of severe infection of his upper respiratory tract and a perianal abscess. He was seen regularly afterwards and improved considerably. On April 30 he weighed 9 lb. 8 oz., seemed contented and slept well, and his pulse and stools were normal. His thyroid gland was no longer clinically enlarged, and his subsequent progress and development were perfectly normal (figs. 1 and 2).

On June 12 he had been started satisfactorily on mixed feeding, weighed 12 lb. 6 oz., had normal motions and a pulse rate of 110. He appeared to be an active, bright, normal baby.

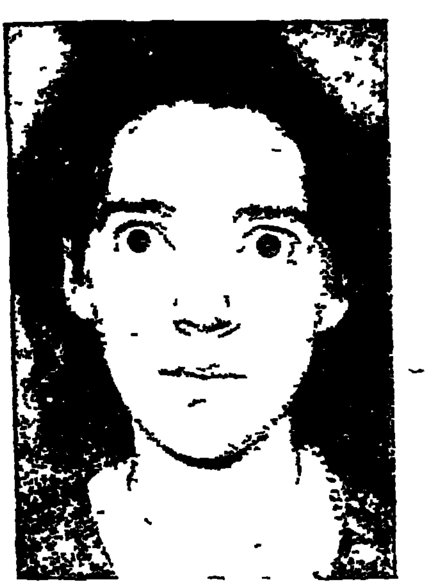

Fig. 3—Exophthalmos in mother of infant with congenital hyperthyroidism.

A month after the birth the mother weighed 9 st.—about 10 lb. less than before the pregnancy. She stated that she had become restless and irritable during the pregnancy, and these symptoms had persisted. Her appetite was good, but she did not regain her normal weight, sweated excessively, and was sure that her eyes had become more prominent. They had felt itchy and weepy, especially in the mornings. She thought that her thyroid gland had begun to enlarge again beneath her operation scar. On examination she was agitated and restless. Her hands were hot, moist, and tremulous, but her pulse rate was only 84. She had striking bilateral exophthalmos and lid retraction (fig. 3) and small nodular thyroid swellings below her scar. Clinically she gave the impression of being moderately thyrotoxic. A radioactive iodine test of her thyroid function was carried out in the out-patient department, but unfortunately one urine sample was accidentally discarded, the sample being passed $6^1/_2$ hours after the dose was given. Excluding this sample, her 48-hour urinary excretion of iodine was only 5.1%, and her protein bound plasma activity after 48 hours was 1.8% of the dose per litre of plasma.

She was subsequently satisfactorily treated with carbimazole.

Discussion

The development of hyperthyroidism in this infant, whose mother had undergone partial thyroidectomy for exophthalmic goitre 11 months before his birth, is yet another example of probable transplacental transmission of maternal thyrotrophic hormone. Congenital hyperthyroidism has only been described in cases where the mother has been thyrotoxic or has had treatment for such a condition. It is often assumed, not necessarily correctly, that exophthalmic goitre is due to overproduction of thyrotrophic hormone (T.S.H.) and to the pituitary's becoming unresponsive to the inhibitory effect of increasing concentrations of thyroid hormone. In such circumstances one would expect that, after operation, the serum-T.S.H. levels would rise because of the continued production of T.S.H., which had previously been inactivated by the thyroid tissue. Certainly such evidence as there is, in the absence of generally applicable assays of T.S.H., suggests that there is such a rise following operations, and Rundle (1945) demonstrated the steady progression of exophthalmos during the first postoperative year. The patient with congenital hyperthyroidism recorded by Koerner (1954) was the offspring of a mother with inadequately treated post-thyroidectomy hypothyroidism, and in such patients Rawson and Starr (1938) and Gilliland and Strudwick (1956) have demonstrated by far the highest detectable serum-T.S.H. levels.

Nikitovitch and Knobil (1955) have suggested that maternal T.S.H. cannot pass the placenta; if this were true in cases of congenital hyperthyroidism, hyperplasia of the thyroid gland in the infant could only be due to overproduction of the infant's endogenous T.S.H. This may happen when the thyrotoxic mother is treated with anti-thyroid drugs, because Freiesleben and Kjerulf-Jensen (1947) have shown that, in rats, thiouracil compounds are transmitted to the fœtus through the placenta. In such circumstances the infant's production of thyroid hormone is inhibited, and it may be born goitrous or even slightly hypothyroid. This, however, seldom happens unless the mother is herself rendered hypothyroid, and no thyrotoxic infant has been born to such a woman, although the mother of the child with congenital hyperthyroidism reported by Fischer (1951) received propylthiouracil towards the end of her pregnancy.

Toxicity in the infant cannot be due to transplacental transmission of maternal thyroid hormone because such toxicity would not be associated with hyperplasia of the infant's thyroid gland. In any case, congenital hyperthyroidism has been reported when the mother has been hypothyroid (Koerner 1954).

Our patient's mother was moderately thyrotoxic, both clinically and on the basis of her metabolism of radioactive iodine. The mothers of the patients reported by White (1912), Margetts (1950), and Fischer (1951) were also thought to be thyrotoxic during pregnancy. Our patient's mother and the mothers of the patients described by Skelton and Gans (1955) had severe exophthalmos, and all of the reported cases of congenital hyperthyroidism have had exophthalmos In view of the accumulating evidence that there is a separate pituitary factor capable of producing exophthalmos, it is of interest that Keynes (1952) reported the birth of a baby with congenital exophthalmos but no evidence of thyrotoxicosis to a mother who had had a thyroidectomy for hyperthyroidism a year previously and developed progressive exophthalmos after the operation

The present baby was undoubtedly thyrotoxic by all clinical criteria, and the result of the radioactive iodine studies showed that, in such a child, iodine metabolism is essentially the same as is observed in the thyrotoxic adult Van Middlesworth (1954) has studied the uptake of radioactive iodine in healthy newborn babies, and in his experience the 24-hour uptake of radioactive iodine by the thyroid gland exceeded 90% in two out of seven children tested on the third day of life He suggests a physiological hyperthyroidism in the newborn infant, because uptakes in his other infants were also greater than are usually observed in normal adults

If the disease is, as we believe, due to transplacental transmission of maternal T S H , it should be self limiting in duration after birth Most of the published cases have in fact been benign, although the patient described by White (1912) died, as did both those of Skelton and Gans (1955) Koerner's (1954) patient was very ill, as were several others , but it appears that, if the hyperthyroidism can be controlled for a few weeks, natural remission will take place For that reason we treated our patient with iodide to overcome the immediate effects of the thyrotoxicosis, and with carbimazole to render him reasonably normal until natural remission occurred Progress as a result of this treatment was entirely satisfactory We believe this was a causal relationship, although there might have been clinical remission even in the absence of treatment

The management of congenital hyperthyroidism is distinct from that of hyperthyroidism developing later in childhood In the congenital case the stimulus that initiates the production of toxicity is derived from the mother, and the condition can be regarded as benign In the later cases, however, the problems are similar to those of adult hyperthyroidism, it being essential to continue treatment with an anti thyroid drug for at least 18 months, and there is, as in adults, a tendency to subsequent relapse possibly necessitating partial thyroidectomy

Summary

A case of congenital hyperthyroidism is reported in the infant son of a woman who had had a partial thyroidectomy for exophthalmic goitre eleven months previously

There was evidence that both mother and infant were thyrotoxic, the infant showing the characteristic features of the disorder, including a goitre, tachycardia, lid retraction, hyperkinesis, restlessness, diarrhœa, and a ravenous appetite, with failure to gain weight

The child was treated with iodide for 10 days and with carbimazole until the age of 3 months Striking clinical improvement coincided with the onset of treatment After treatment was stopped his subsequent progress was satisfactory and normal

It is believed that congenital hyperthyroidism is due to transplacental passage of maternal thyrotrophic hormone and that the resulting hyperthyroidism in the infant is normally self limiting

We are grateful to Dr D N Nicholson under whose care this patient was treated for his interest and to Sister Jean Wood for her skill and help in the collection of the infant s urine One of us (A G M) is in receipt of an expenses grant from the Secretary of State for Scotland through the Advisory Committee on Medical Research

NEURONE SELECTION IN RELIEF OF PAIN

FURTHER EXPERIENCES WITH INTRATHECAL INJECTIONS

R M Maher

M D Lond , B Sc Lpool, M R C P

CONSULTANT PHYSICIAN, ROCHDALE HOSPITAL GROUP ,
CONSULTING PHYSICIAN, COUNTY BOROUGH OF OLDHAM

In heavy conveying solvents, phenol or silver nitrate can be injected intrathecally so that they flow over a series of posterior-root ganglia to relieve pain in cancer The solvents used are glycerin or ' Myodil ' (ethyl iodo phenylundecylate) Propylene glycol was abandoned as dangerous (Maykut and Ryan 1953) Since my last paper (Maher 1955) and after experience with over 125 cases, improvements in technique have been evolved for example, (*a*) I no longer use heavy cinchocaine hydrochloride (' Nupercaine ') before the phenol injection, (*b*) the dose and strength of the agents used have been better adjusted , and (*c*) injections are now given in the epidural and subdural layers, as well as below the arachnoid With reasonable care, the method is safe and some 90 punctures have been carried out in the cervical region alone

Solutions Used

Phenol alone (1 in 20).—1 g of phenol crystals is quickly weighed and placed in a dry sterile 30 ml bottle A sterile rubber cap is applied 20 ml of sterile glycerin or myodil is injected through the cap to give a 1 in 20 solution Smaller amounts can be prepared proportionately and the solution will keep for two weeks Weaker solutions do not afford permanent relief, and stronger solutions may cause unwanted effects (table I)

Phenol with silver nitrate.—Gr $2^1/_2$ (0 16 g) of silver nitrate are weighed and placed in a sterile 30 ml bottle A sterile cap is fitted 8 ml of sterile distilled water is injected through the cap When the phenol has dissolved, 1 ml of this solution is added to 24 ml of phenol solution (1 in 25) in glycerin 1 ml of this mixture, which contains gr $^1/_{80}$ (0 75 mg) of silver nitrate, is the usual dose If stored in the dark the solution will keep for three weeks

TABLE I—EFFECTS OF DIFFERENT STRENGTHS OF SOLUTION WHEN INJECTED INTRATHECALLY

Grade of change	Phenol in glycerin or myodil (1 ml)	Relief	Cutaneous analgesia	Cutaneous anæsthesia	Proprioceptive sensation	Motor function
I	1 in 30	Immediate not permanent	Nil	Nil	No effect	No effect
II	1 in 20	Permanent	Usually nil	Nil	No effect	No effect
III	1 in 15	Permanent	Definite	Scattered	Variable	No effect
IV	1 in 10	Permanent	Severe	Severe	Impairment of limb	

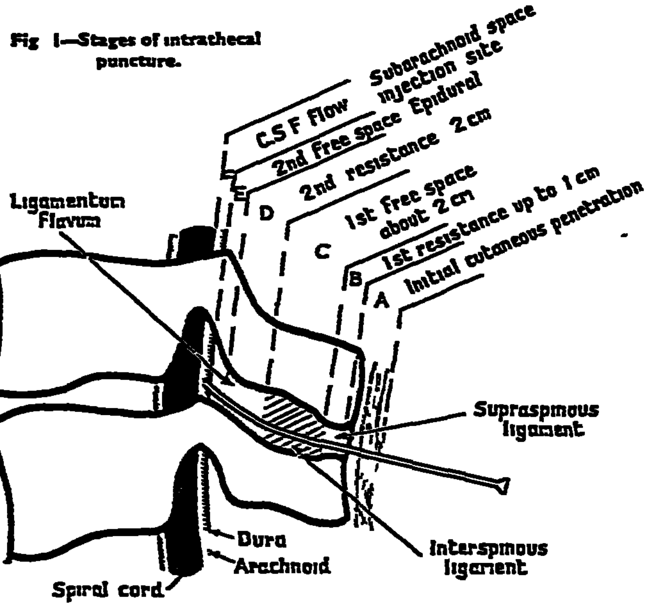

Fig 1—Stages of intrathecal puncture.

Local anæsthetic.—Cinchocaine hydrochloride was at first used as a safety measure before the phenol was injected, but it was found to be unnecessary Without cinchocaine, the immediate approximates more closely to the final result When there has been no previous anæsthesia, it is certain that any relief of pain is due to the phenol. It is also possible to assess the effects of different strengths of phenol.

Subarachnoid Injections

TECHNIQUE

Spinal Puncture

The patient is seated upright If possible it is preferable to puncture at one segment higher than the involved neurones so that the agent flows caudally The epidural space is easily located by gauging the resistance to the needle and repeatedly injecting procaine The theca is then penetrated The following stages are illustrated in fig 1

(A) Procaine (2% solution) is injected subcutaneously using a fine needle (26 gauge ½ in.)

(B) Further infiltration is made into the interspinous ligament and beyond The lumbar-puncture needle (Howard Jones type 21 gauge 3½ in) is then entered at rather less than 90 to the skin the shank being lower than the point It must enter the interspinous ligament at the peak of the interspinous ridge

(C) It passes easily for about 2 cm., procaine is injected continuously and flows freely

(D) A gripping resistance is felt and the needle can be safely pushed forwards for as long as this continues As it proceeds progressively less procaine can be injected—a sign of probable success

(E) The needle suddenly seems to ride over a ridge and the procaine flows freely in the epidural space

(F) It is then advanced 2 mm without the stylet cerebrospinal fluid (C.S.F.) will flow and the stylet is replaced

Position for Injection

Position I (for lumbar and high sacral injection)—The patient is laid on the painful side in the lateral lumbar-puncture position and rotated slightly backwards with a very slight downward slope of the spine towards the sacrum

Position II (for S4–5 segments)—He remains vertical during the injection at L5–S1 interspace

Trial Injection of Phenol

This is made when the pain is at a maximum to ensure that all the affected roots are reached To reach roots at the lumbar level the injection is made at the L1–2 or L4–5 interspace using position I 1 ml of phenol (1 in 20 in glycerin or myodil) is the standard dose First 0 5 ml is injected Pain should diminish and the remaining 0 5 ml is immediately injected The slope of the spine is increased as much as is necessary *to relieve all the pain*

To reach roots at the dorsal and cervical levels 3–3 5 ml of phenol (1 in 20 in myodil) is used Using position I, the injection is made at C3–4 interspace (for occipital pain) or C5–6 interspace (for brachial-plexus pain) The position of each 1-ml. dose is confirmed radiologically. Using position II for the sacral segments 1 5 ml of the solution is given in the L5–S1 interspace The limbs should be rested for three days afterwards

Total relief for five days indicates that no further injection is needed in that area

Supplementary Injections

For permanent relief, the initial pain-relieving injection must be followed usually after five days, by injections in other areas covering all adjacent predictable pain patterns 1 ml of the phenol solution covers about 4 to 6 segments at a session By further injections at different adjacent levels, using 1 ml for each it is possible to denude a patient of all pain fibres bilaterally below umbilical level without cutaneous sensory change or severe side-effects Fig 2 illustrates the usual injection range for pelvic cancer and for sarcoma of the lower limb, which usually involves injection at D12–L1 and L3–L4. For cancer of the rectum these segments are used after a vertical injection in position II has been allowed to gravitate to the tip of the dural sac for the lowest sacral and coccygeal elements This may cause temporary retention of urine For cervical- or brachial-plexus segments, one injection of 3 5 ml. of phenol (1 in 20 in myodil) is sufficient

When the initial phenol injections do not give adequate relief the phenol and silver-nitrate solution can be used at resistant sites after a few days. It is of particular value in cancer in the pelvis primary or secondary.

Side-effects

Before and after injection morphine is given if necessary, and if there is severe pain it may be relieved by

0 3 ml of cinchocaine hydrochloride injected through the needle There are often attacks of pain or lightning pains for a week before relief is felt In 2 cases injection of silver nitrate (gr $^1/_{20}$) was followed by a meningitis (800 cells per c mm in the C S F) There were no after-effects, however, and relief lasted for over a year

Variations

Because the solution tends to accumulate below L1, the dosage of phenol solution (1 in 20) has to be limited to 1 ml Above this vulnerable stretch, the dose can be increased, and curiously the cervical region can take at least 3 5 ml of phenol solution (1 in 20) Possibly this is due to longer and narrower root pockets in this region

Increased strength (up to 1 in 15) can be used above *the L1 level A strength of 1 in 10 seems* to give cutaneous anæsthesia, bedsores, and muscular impairment Although this is not cord damage, it is functionally equivalent to it

The effect of sterile water, added to 1 ml of phenol solution (1 in 20), varies with the amount added 0 1 or 0 2 ml enhances the effect, and 0 3 ml *leads to effects* of grade III or IV (table I) Equal parts of water and phenol in 2 extreme cases diffused to the cord, producing profound anæsthesia, and, after a few days, loss of power Dry phenol in the conveying agent never affected the cord even on direct application

RESULTS

I have now treated 106 patients with severe pain by these methods Most of them experienced relief but in 33 of them the pain returned in a few hours Necropsy was done in 17 of these failures, and there was gross metastasis in the spine of all of them Fig 3 shows carcinoma cells in the posterior root ganglion in one of these 3 further patients who got no immediate relief showed no motor or sensory change whatever, even with phenol 1 in 10 the spinal canal at necropsy was found completely occluded by growth

In the failures, therefore, immediate relief suggests action only on the fibres of the posterior root (nerve-fibre block) Absorption of phenol in the fibres must be very rapid because no extension of cutaneous sensory change occurs on tilting the spine further a few minutes after the injection I infer that in successful cases, phenol affords permanent relief only by selection of the smaller cells of the posterior root ganglia (nerve cell block) If these cells are sheltered from the phenol by areas of carcinoma, permanent relief cannot be expected

There is further evidence to suggest such sheltering

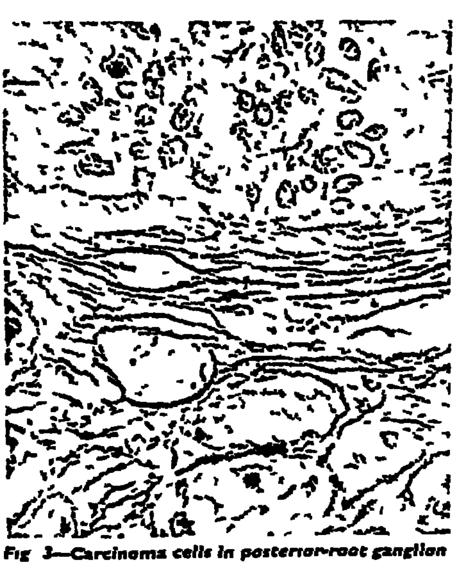

Fig 3—Carcinoma cells in posterior-root ganglion

(1) With pelvic cancer, injection for the femoral components alone often gave total relief When this had lasted for some weeks, a so-called "return of pain" was often now felt in the sciatic group of dermatomes (L4,5, S1 2 3) (fig 2) If phenol was injected dually, total relief continued in 1 case lasting for a year afterwards Both femoral and sciatic nerves were involved simultaneously in 16 cases, of these only 3 were relieved The failures had relief only *in the recently invaded nerve group* This suggests that there had been long-standing perineural spread to the ganglia along the femoral elements with more recent impingement on the sciatic group, or vice versa

(2) In cases resistant after injection, the total pain area was often reduced to one or two points Further phenol injection even at 1 in 10 strength made no difference to these points

(3) The length of nerve between the growth and the cord influenced the results All cases of sarcoma of the lower limb were totally relieved, even at a late stage Here, however, there is a different form of spread Of 16 cases of pulmonary cancer, only 6 were relieved here pain often begins when the growth leaves the lung border adjacent to the vertebral column, and having only 2 cm to travel, the growth rapidly invades the ganglia and the pain becomes intractable Horner's syndrome is a sign that metastases are involving the roots, cordotomy is indicated In 1 such patient pain was reduced, by injection, to an intractable ulnar distribution corresponding *to the roots involved in* Horner's syndrome By contrast, carcinoma in the pelvis has a comparable perineural travel length of some 16 cm Of 14 cases of carcinoma of the rectum, 10 were successful, with uterine cancer, 19 out of 28 patients were relieved

TABLE II—RELATION OF DURATION OF PAIN TO RELIEF

Duration of pain (months)	No of patients	No relieved	No unrelieved
Less than 1	11	10	1
1–3	29	23	6
4–12	42	25	17
Over 12	24	11	13
Total	106	69	37

Since infiltration of a ganglion takes time to develop it was decided to regroup cases according to how long *they had had pain and to* compare the results attained (table II) Within limitations imposed by the rate of extension of the growth and the distance it must travel, the prospects for relief depend largely on the duration of the pain before injection The outlook seems independent of the stage of the growth and of the intensity of the pain *The chance of relief seems best when pain has* been present for less than a month, especially in lung cancer, with its relatively short distance from the root ganglia

Of 26 cases of pelvic cancer not relieved by phenol alone, 15 were relieved by the injection of phenol with silver nitrate at lumbar level Injection was usually made at the same interspace as the previous unsuccessful phenol injection Injection in the dorsal region in 4 cases relieved pain permanently in gastric and renal cancer For cervical and upper dorsal sites it was unsuccessful and considered unsafe

In contrast to phenol, silver nitrate, at whatever strength, merely selected pain neurones without causing disability Increase in strength increased meningeal reaction Silver nitrate tended to "fix" a temporary phenol effect to make it permanent, and it became possible to employ phenol 1 in 25 with gr $^1/_{80}$ silver nitrate in 1 ml of vehicle Recently this has been added to myodil and used as an initial injection

Other Methods

Extra-arachnoid injections were most often used in the cervical region A Howard Jones needle (18 gauge $3^1/_2$ in) with a short bevel point is used, with the patient in position I Careful local anæsthesia using 2% procaine up to the epidural space (E in fig 1) is necessary Then the needle is carefully pushed forwards to prod the dura This gives a sharp sensation After the needle has been rotated through 180°, 1 ml of phenol solution (1 in 20 in myodil) is injected *Its position is confirmed radio*

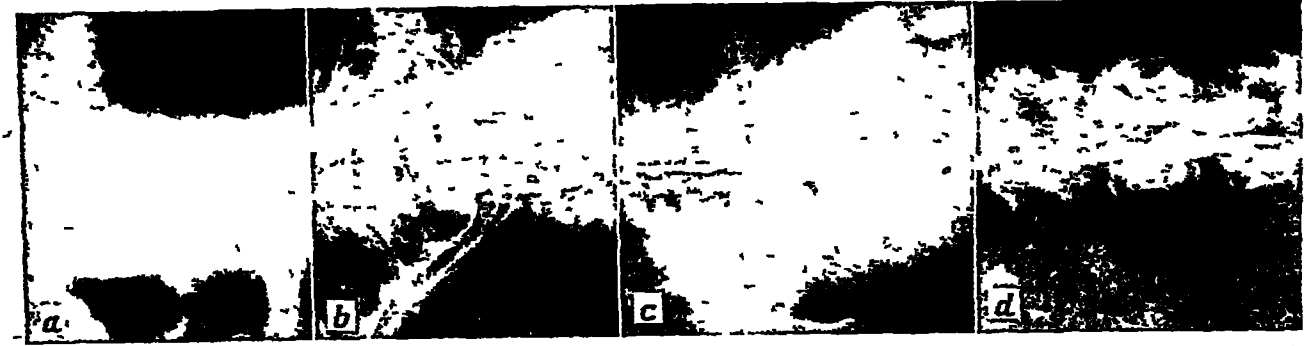

Fig 4—Injection at different thecal layers (a) epidural injection taking the segmental shape of the spinal canal, (b) subdural injection with root travel into the brachial plexus, (c) intrathecal injection (' oil-in the-water-bath ' appearance) (d) " double-line ' block of both intra- and extra-arachnoid injection

logically (fig 4*b* shows bilateral flow towards the root exits) 2–3 ml of the agent is then injected, followed by a further radiograph

Phenol in myodil subdurally has the following effects

(1) It runs bilaterally in a cephalic direction towards the roots on each side, although the patient lies in position I

(2) It tends to divide into portions opposite the root exits

(3) It travels along the nerve roots, mostly on the ' downward ' side In doing so it would tend to surround the ganglia thereby overcoming the effect of sheltering

The subdural space was reached in 7 cases and excellent relief was obtained in all of them

By combining subarachnoid with subdural or even epidural injections (double-line block), there should be more certainty of reaching all sides of the ganglia Here subdural injection of 2–3 ml of phenol solution (1 in 20 in myodil) is followed by further advance of the needle through the arachnoid where 1 ml of the same agent could be injected intrathecally at lumbar level or 3 ml at cervical level Fig 4*d* illustrates double line block with the meningeal lining showing as an interval

Non-malignant Conditions

Since there is no sheltering by tumour tissue, relief would be expected in non-malignant conditions treated by subarachnoid injection But inpatients with arthritis and scoliosis, an irregular spinal canal and osteophytes often make injections hazardous 3 patients with spondylitis showed relief and better movement Of 12 arthritic patients 4 were relieved but 8 developed acute exacerbations with generalised pains even after small doses Intrathecal injection is therefore usually contra indicated for arthritis

1 patient with post herpetic neuralgia was completely relieved Severe and continuous flexor spasms in a case of hemiplegia ceased permanently after injection, with improved movement of the leg Dr Peter Nathan, of the National Hospital for Nervous Diseases, alleviated 3 further cases of flexor spasms by this method Subdural and epidural injections of 1 ml of phenol solution (1 in 20 in myodil) give good relief in 2 or 3 cases and seem a safer measure for non malignant conditions

Conclusions and Discussion

The chance of successfully relieving the pain of cancer varies directly with the distance of the growth from the ganglia and indirectly with the duration of the pain

In an outpatient department where a cancer patient attends when his pain begins, it is easy to deal with it then and there using a phenol trial injection at the required level One or two successive injections at weekly intervals will cover neighbouring segments and prolong the relief by forestalling further extension of the growth If the pain is resistant phenol with silver nitrate should be used after admission to hospital The addition of subdural injections may further improve the chances of relief A Pain Relief Centre has been set up in this area to encourage early treatment

Better agents may be found in the future and the principle of neurone selection using gravitational flow may find a wider use But for cancer, unless they are done early, such procedures will continue to have the same doubtful reputation for haphazard results For pain from non-malignant causes extra arachnoid methods are probably safer

Summary

A technique for arachnoid puncture at all spinal levels has been evolved for the relief of severe pain With 1 ml of a 1 in 20 solution of phenol pain fibres only were affected, and there was no cutaneous sensory change, extensive areas on both sides can be treated

Success was more likely when the pain was of relatively recent onset Further pain-forestalling injections in adjacent segments were necessary for permanent relief

Resistant pain may be partly due to ' sheltering " of nerve cells from the phenol solution by areas of growth in the posterior-root ganglia Phenol with silver nitrate afforded relief in a number of cases resistant to phenol alone

Subdural injection may prove useful in conditions other than cancer Subarachnoid injection of phenol is useful for flexor spasm, but is not recommended for arthritis

My great thanks are extended to Dr Ralston Paterson Dr E C Easson Dr and Mrs J Starkie, Dr Helen Russell, Mrs M Laycock Mr F Inston and Mr A B Miller, M P S I should also like to thank Sir Geoffrey Jefferson F R S, Mr R T Johnson and Dr Reginald Reid, of the neurosurgical department, Manchester Royal Infirmary, for their help

" The Public Health Service is composed of two separate but related parts. On the one hand there is the House-keeping Service—providing ambulances nurses, inspectors and the other health and welfare services for the community that can best be done in a communal fashion On the other hand there is another more important duty that is being neglected, namely, long term enquiry The sort of investigation and action which a hundred years ago was made with assurance of profitable result, is no longer available to us Progress will be halting and hesitant and difficult to achieve We are, however, passing through one of the great social experiments and we are not taking note of where we are going, nor of the results of our efforts, for all our social experiments will bring bad as well as good results *Noise hurry* long life, new techniques good and hardful, accompany our progress and we accept them with an alarming complacency The preoccupation of the Department for the chores is leaving little time for enquiry, and young men with an enquiring mind are not entering the service Never was patient social research so needed, and probably never so revealing ' —Dr LLEWELLYN ROBERTS, medical officer of health for Sheffield, in his report for 1955

HOMOZYGOUS HÆMOGLOBIN-E DISEASE IN INDONESIA

LIE-INJO LUÁN ENG
M D, D T M &H
SENIOR ASSISTANT

OEY HOEY GIOK
MEDICAL STUDENT

DEPARTMENT OF PARASITOLOGY AND GENERAL PATHOLOGY,
UNIVERSITY OF INDONESIA, DJAKARTA

SINCE the discovery of hæmoglobin E in 1954 by Itano et al (1954) in a family of partly Indian origin and simultaneously by Chernoff et al (1954) in the Siamese, this abnormal pigment has been observed in Veddas from Ceylon (Graff et al 1954), in Indonesians (Lie Injo Luan Eng 1955a), and in Burmese (Lehmann et al 1956)

Three conditions associated with this abnormal pigment have been recognised the hæmoglobin E trait, which is the heterozygous form for the gene of this abnormal hæmoglobin, pure hæmoglobin E disease, representing the homozygous state, and hæmoglobin E/thalassæmia disease, representing the double heterozygous state for the hæmoglobin-E and the thalassæmia genes

Six cases of pure hæmoglobin E disease have been reported from Thailand (Chernoff et al 1956) and two in Burmese (Lehmann et al 1956), but in no case was it possible to study both parents to prove the homozygosity of the condition

We report here three cases of pure hæmoglobin E disease in Indonesians In two of the three cases both parents were carriers of hæmoglobin E

Methods

All pipettes and counting chambers used for hæmatological determinations carried the certificate of the U S National Bureau of Standards Observations were made in duplicate Fœtal hæmoglobin in the blood was estimated by the method of alkali denaturation described by Singer et al (1951) For normal adults 2% alkali-resistant hæmoglobin of the total amount of hæmoglobin was taken as the upper limit of normal (Singer et al 1951, Lie Injo Luan Eng 1955b)

Hæmoglobin was analysed by paper electrophoresis according to the method described by Smith and Conley (1953) with veronal buffer pH 8 6 and ionic strength 0 05 and phosphate buffer pH 6 5 ionic strength 0 1 Serum-bilirubin and urobilin and urobilinogen in the urine were examined in the laboratory of the Central General Hospital, Djakarta

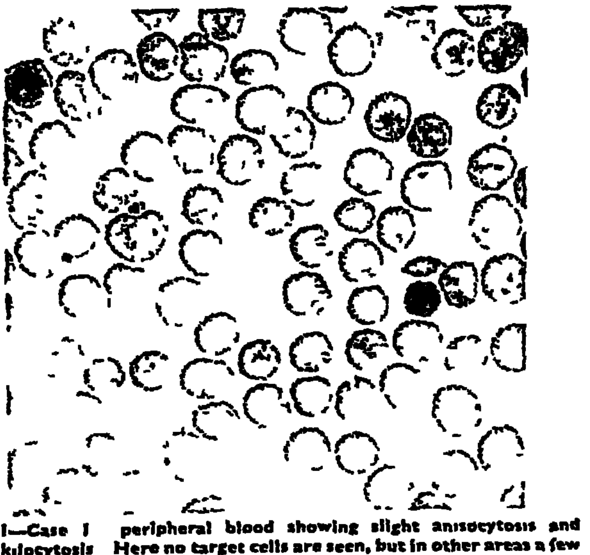

Fig 1—Case 1 peripheral blood showing slight anisocytosis and poikilocytosis Here no target cells are seen, but in other areas a few target cells were found (× 837)

Case-reports

Case 1—A girl, aged 9 years, was examined only because, during a survey on pathological hæmoglobins in the wards of the Central General Hospital in Djakarta her mother, who was being treated for chronic bronchitis was found to be a carrier of hæmoglobin E trait The whole family was therefore examined, and it was found that case 1 the eldest child had pure hæmoglobin E in her blood, and her father was a carrier of hæmoglobin E trait The family came from Padang in Sumatra So far as they knew they were pure Indonesian. The girl did not feel ill but, according to her mother, she was not strong, was easily fatigued, and had always looked somewhat pale She had never had icterus

Physical examination on Jan 31, 1956 showed that she was in good nutritional state and did not look ill but seemed slightly anæmic Her lymph nodes were not enlarged heart and lungs were normal, and spleen and liver both slightly enlarged, firm, and not tender No other physical abnormalities were noticed

Radiography of her skull, long bones, metacarpals and metatarsals, thorax, vertebræ, and pelvis did not show any abnormality Her lungs and heart were also normal on radiography

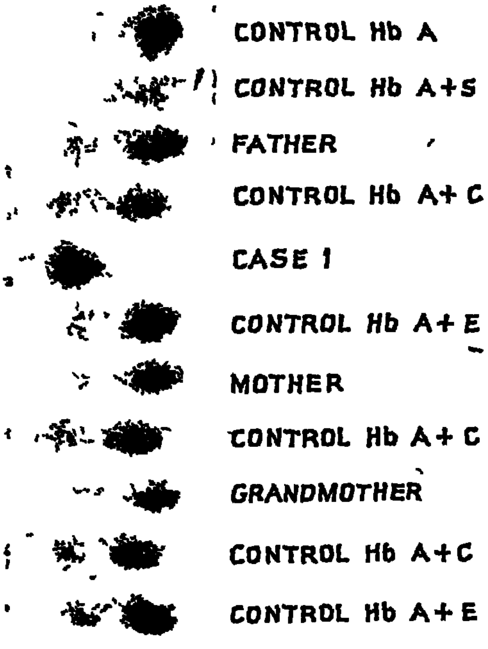

Fig 2—Paper electrophoresis at pH 8 6 of hæmoglobin of case 1, her parents and her grandmother compared with controls

Laboratory findings—Hæmatological data are summarised in table I There was slight erythrocytosis and microcytosis The mean corpuscular hæmoglobin concentration (M C H C) however, was normal The changes in the peripheral blood were not obvious (see fig 1) There were only slight poikilocytosis and anisocytosis No normoblasts were seen There were no Howell Jolly bodies and no rings of Cabot, but there were a fair number of cells with basophil stippling Only a few target cells were seen There was also a slight reticulocytosis A sickling test with 2% sodium metabisulphite was negative No malarial parasites were observed The resistance of the erythrocytes to hypotonic saline solution was increased The amount of alkali resistant hæmoglobin was found not to be increased Paper electrophoresis of the hæmoglobin at pH 8 6 showed only one type of hæmoglobin having a mobility which seemed to be similar to that of hæmoglobin C However since both parents were found to carry hæmoglobin E with a mobility higher than that of hæmoglobin C, it was expected that the child had hæmoglobin E and not hæmoglobin C Indeed at pH 6 5 the mobility was found to be definitely less than that of hæmoglobin C When the child's hæmoglobin was mixed with normal hæmoglobin so that the relative concentrations of the abnormal and the normal component were about the same as in a trait carrier the abnormal component had the same mobility at pH 8 6 as that of

TABLE I—LABORATORY FINDINGS IN CASE 1 AND FAMILY

—	Case 1	Mother	Father	Sister	Brother	Grandmother
Age when examined	9 yr	45 yr	50 yr	3 yr	13 mos	70 yr
Hb (g per 100 ml)	10 9	11 6	14 4	11 9	10 2	11 9

* Saline fragility initial at	0 40 %	0 40 %	0 40 %	0 40 %	0 40 %	0 40 %
complete at	0 20 %	0 28 %	0 24 %	0 28 %	0 20 %	0 32 %
Hijmans van den Bergh reaction direct/indirect	Not increased	Not increased	Not increased	Not increased	Not increased	Not increased
Alkali resistant hæmoglobin (% of total)	1 3	1 1	1 0	0 8	1 7	1 0
Hæmoglobin analysis	E	A + E	A + E	A	A + E	A + E
Urobilinuria	+	—	—	—	—	—
Spleen enlargement	±	—	—	—	—	—
Liver enlargement	+	—	—	—	—	—
Malaria	—	—	—	—	—	—

* Control determinations of the osmotic saline fragility in normal persons showed initial hæmolysis at 0 44–0 40 % (mostly at 0 44 %) complete hæmolysis at 0 32–0 28 % (mostly at 0 32 %)

hæmoglobin E and was slightly faster than hæmoglobin C It was therefore evident that the child had pure hæmoglobin E (see fig 2) The serum bilirubin level was not raised The urine contained urobilin and urobilinogen but no bilirubin or albumin In the fæces a few eggs of *Ascaris lumbricoides* were found but no other parasites or other abnormalities Bone marrow puncture was unfortunately not allowed

Progress—After three weeks' iron therapy there was no hæmatological improvement The amount of alkali resistant hæmoglobin was again found not to be increased

Family

The mother, aged 45, had chronic bronchitis, was very thin, and looked ill Her heart was normal, her spleen and liver were not enlarged The laboratory findings are summarised in table I

The father, aged 50, was healthy, no abnormalities being found on physical examination His spleen and liver were not enlarged The laboratory findings are summarised in table I He was a carrier of hæmoglobin E trait

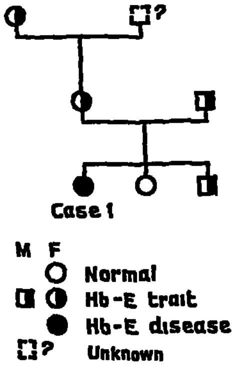

Fig 3—Pedigree of case 1

The second child, a girl aged 3 years, was not ill On physical examination no abnormality was found except slight rhinitis Her spleen and liver were not enlarged The laboratory data are summarised in table I The hæmatological findings were within the normal range for her age except for eosinophilia Her hæmoglobin was of the normal type

The youngest child, a boy of 13 months, was dystrophic and had influenza, diarrhœa, and bronchitis His spleen and liver were not enlarged The laboratory findings are listed in table I He was found to be a carrier of hæmoglobin E trait

The grandmother of case 1 was aged 70 and healthy On physical examination no abnormalities were found Her spleen and liver were not enlarged She was a carrier of hæmoglobin E trait (fig 2 and table I) Other laboratory findings are also listed in table I

The pedigree of this family is shown in fig 3

Case 2 —An Indonesian soldier, aged 36, from the island of Timor was registered as a regular donor at the Blood Transfusion Service of the Red Cross in Djakarta When he gave 500 ml of blood on May 9, 1956, a small amount was taken for routine survey of pathological hæmoglobins, and his erythrocytes were found to contain pure hæmoglobin E We studied him further on July 7, 1956 He said that he was quite healthy, was very seldom ill and did his heavy job without any complaint He had never had anæmia or icterus He was married and had two healthy children

On physical examination he was in a good nutritional state and not anæmic There was not the slightest icterus His lymph nodes were not enlarged, his lungs and heart were normal, and his liver was not enlarged, but his spleen was just palpable one finger breadth below the costal margin, firm, and not tender

Radiography of his skull, long bones, metacarpals and metatarsals, thorax, vertebræ, and pelvis did not reveal any abnormality

Laboratory findings on July 23, 1956, are listed in table II There was microcytosis but no anæmia The M C H C was normal The peripheral blood showed only slight anisocytosis but there were numerous target cells (fig 4) Red cells with basophil stippling were present The number of reticulocytes was not increased The numbers of leucocytes and of thrombocytes were normal A sickling test with 2% sodium metabisulphite was negative No malarial parasites were found The resistance of the red cells to hypotonic saline solution was increased The serum bilirubin level was not raised Electrophoresis showed only hæmoglobin E (fig 5) The percentage of alkali resistant hæmoglobin was within normal limits The urine did not show any abnormality

Family

On Sept 14, 1956, the parents of case 2 could not be examined, but we examined his wife and two children

The wife did not feel ill She was two months pregnant On physical examination no abnormalities were found The laboratory findings are shown in table II She was a carrier of hæmoglobin-E trait

The elder child, a girl aged 3 years, had pure hæmoglobin-E disease (see case 3)

The second child, a boy aged 1 year, had rhinitis and was very often ill with pyrexia He had had dysentery of undetermined ætiology two months before examination On physical examination he was found to be somewhat dystrophic The

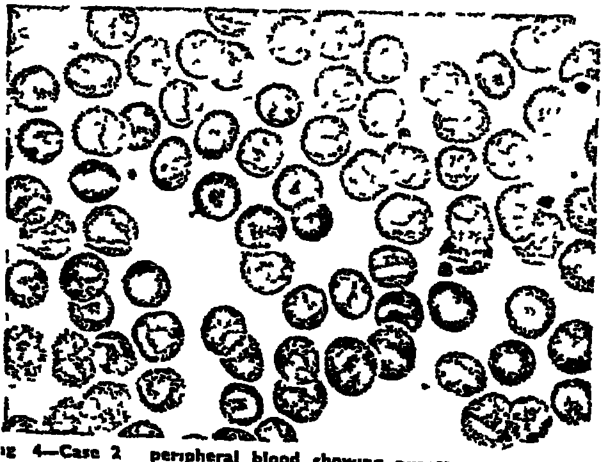

Fig 4—Case 2 peripheral blood showing numerous target cells (× 837)

TABLE II—LABORATORY FINDINGS IN CASES 2 AND 3 AND FAMILY

	Case 2	Wife	Case 3 (daughter)	Son
Age when examined (yr)	36	21	3	1
Hb (g per 100 ml)	14 5	13 5	13 0	10 9

Spleen enlargement	+	−	−	−
Liver enlargement	−	−	−	−
Malaria	−	−	−	−

laboratory findings are shown in table II In his fæces no abnormalities were found He was a carrier of hæmoglobin E trait

Case 3 —A girl, aged 3 years, daughter of case 2, was healthy She was in a good nutritional state and very seldom ill On physical examination no abnormalities were found Her spleen and liver were not enlarged Her heart and lungs were also normal The laboratory findings are shown in table II Her hæmoglobin was within normal limits for her age There was a clear microcytosis of the erythrocytes The mean *corpuscular hæmoglobin was normal* The peripheral blood showed slight anisocytosis Target cells were present but not so numerous as in her father's blood Basophil stippled cells *were not found The number of reticulocytes was not increased* A sickling test with 2% sodium metabisulphite was negative No malarial parasites were found The resistance of the erythrocytes to hypotonic saline solution was increased Electrophoresis of the hæmoglobin revealed hæmoglobin E and a trace of fœtal hæmoglobin The amount of alkali resistant hæmoglobin was 6% of the total amount No abnormalities were found in the urine The fæces contained a few eggs of *Trichocephalus dispar*, no other parasites

Discussion

It is not strictly permissible to describe a person as homozygous for a gene responsible for an abnormal hæmoglobin unless the diagnosis by electrophoresis has been confirmed by a study of his family (Lehmann et al 1956, Chernoff et al 1956) It is known that the laboratory findings in sickle cell/thalassæmia disease may be indistinguishable from those found in homozygous sickle cell disease Analogous to this, certain cases of hæmoglobin-E/thalassæmia *disease indistinguishable from* homozygous hæmoglobin-E disease might also be found In such cases only study of the family would be conclusive

In none of the few cases of pure hæmoglobin E disease published up to now were both parents studied Therefore the *homozygosity of the cases was not entirely* proved

In all three of our cases the diagnosis by electrophoresis was pure hæmoglobin-E disease In case 1 the diagnosis was confirmed by a *family study, both parents being* carriers of hæmoglobin-E trait, and no thalassæmia factor being found in this family

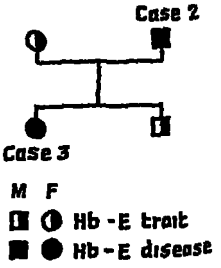

Fig 6—Pedigree of cases 2 and 3

The parents of case 2 were not examined, in case 3 both parents were carriers of hæmoglobin E, but a thalassæmia factor in the father could not be entirely ruled out

As one of us (Lie-Injo Luan Eng 1956) has pointed out, in comparing hæmoglobin types one should compare *them in similar* conditions The pure form of a hæmoglobin type should not be compared with the trait form, because this can lead to a wrong conclusion (fig 2) This is especially important when one has to differentiate two hæmoglobin types showing *only* a slight difference in mobility—e g, hæmoglobin E and hæmoglobin C at pH 8 6 If one compares the mobility of the hæmoglobin of case *1 with hæmoglobin C found in the control* trait hæmoglobin C (fig 2), the wrong conclusion could be reached that the hæmoglobin found in case 1 was hæmoglobin C However, both parents and the grandmother of case 1, who were trait carriers of the abnormal hæmoglobin had a pathologic component in their hæmoglobin with exactly the same mobility as that of hæmoglobin E being slightly greater than that of hæmoglobin C However, *the relative mobilities seen on paper* electrophoresis are not entirely constant, owing to factors which we do not yet understand Small differences are therefore difficult to assess and one must repeat the procedure several times before one can be sure of the constancy of the differences in relative mobility on paper electrophoresis Electrophoresis at an acid pH will help in making an accurate diagnosis This has been pointed out by H A Itano (personal communication) Also at pH

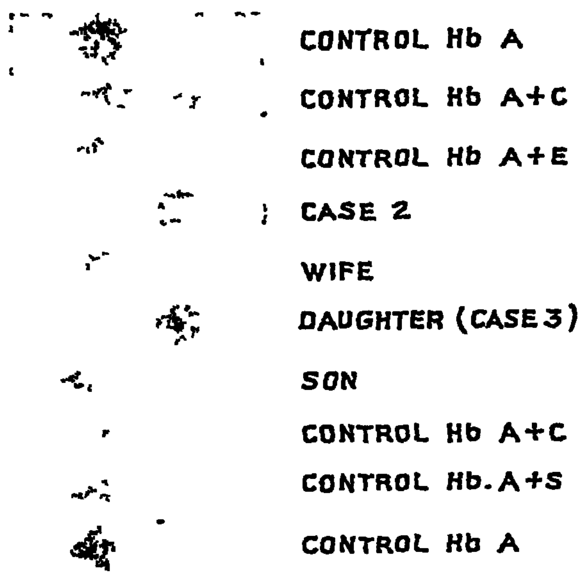

Fig 5—Paper electrophoresis at pH 8 6 of hæmoglobin of case 2 case 3, and family

6·5 one should compare hæmoglobin solutions under similar conditions. We found that, at this pH, the pure form of hæmoglobin E seems to have a mobility slightly greater than that of hæmoglobin E found in the trait condition. Study by open-boundary electrophoresis is more accurate, but this method is available only in a few laboratories and is impracticable for the mass survey.

The clinical picture in case 1 resembled that described in the cases of Chernoff et al. (1956). She complained of easy fatigability and tiredness; her spleen and liver were slightly enlarged, and she had slight anæmia. Case 2 resembled the cases described by Lehmann et al. (1956). He was entirely healthy and led a very active life without any complaint. His spleen was only just palpable. There was not the slightest anæmia. Case 3 also was healthy and had no anæmia. In all our cases the blood showed microcytosis and the M.C.H.C. was normal. The resistance of the erythrocytes to hypotonic saline solution was increased. In all three cases there was no clear evidence of increased hæmolysis. In cases 1 and 2 the amount of fœtal hæmoglobin was not increased. In all the published cases the amount of alkali-resistant hæmoglobin was slightly increased, ranging from 2% to 6·4% of the total amount of hæmoglobin (Chernoff et al. 1956, Lehmann et al. 1956). Case 1 had only a few target cells in her peripheral blood. Other workers have always found numerous target cells in the peripheral blood of cases of pure hæmoglobin-E disease.

The two other conditions associated with hæmoglobin E in the blood are the trait hæmoglobin E and hæmoglobin-E/thalassæmia disease. In a study of 15 families it was found by one of us (Lie-Injo Luan Eng 1956) that the heredity of hæmoglobin E fits the theory that this gene is transmitted as a mendelian dominant factor, and that this gene is an allele of the gene for normal hæmoglobin. Carriers of the trait are heterozygous for the gene for hæmoglobin E. They are clinically asymptomatic. But hæmatological study of 36 carriers of hæmoglobin-E trait by Chernoff et al. (1956) and of 44 by Lie-Injo Luan Eng (1956) revealed that many of the trait carriers showed slight microcytosis of the erythrocytes, and that the resistance of the red blood cells to hypotonic saline solution was sometimes increased.

The gene for hæmoglobin E has been found in many countries in South East Asia and plays an important rôle in this part of the world. The distribution of hæmoglobin E in Asia has been discussed by Lehmann et al. (1956). In a survey of about 4000 samples of blood from different islands in Indonesia hæmoglobin E was found on all the islands examined (Lie-Injo Luan Eng 1956). On the island of Java the approximate incidence is 3%. On the island of Madura, however, the incidence is much higher—about 17% (Lie-Injo Luan Eng unpublished).

Hæmoglobin-E/thalassæmia disease has been described especially by Chernoff et al. (1956) and by Lie-Injo Luan Eng (1956). Both clinical and laboratory findings were very variable. Different hæmoglobin patterns—namely, E + F, E + A, and E + A + F—were found by Lie-Injo Luan Eng (1956). The syndrome was very like that found in Cooley's anæmia.

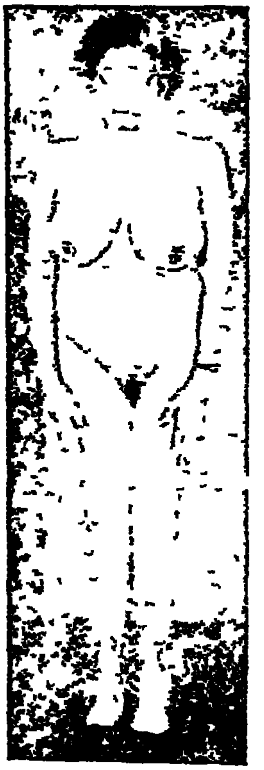
Cushing's syndrome is usually associated with hyperplasia, hyperfunction, or tumours of the adrenal cortex whose secretions are responsible for the clinical and metabolic features of the disease. A few cases, however, have been described in association with carcinoma of the bronchus, pancreas, or thymus (Thorne 1952), cerebral lesions (Zondek 1923), diseases of the liver (Bongiovanni and Eisenmenger 1951), and tumours of the ovaries. The relation between the syndrome and these lesions is not understood. The patient whose case we report here suffered from Cushing's syndrome and a carcinoma of the bronchus, and showed other unusual features which suggested the presence of a functioning carcinoid tumour.

Case-report



A woman, aged 55, was first seen by one of us (A. S. R.) at the Lagan Valley Hospital, in September, 1955, complaining of pustular spots on the legs and arms, and growth of hair on the face. Her menstrual periods had ceased 2 years previously and there were no past illnesses. Her mother had had diabetes mellitus, but there was no indication that this might have been due to Cushing's syndrome. She had a stout body and thin limbs, and there were pads of fat in the supraclavicular triangles, axillæ, groins, and cervicodorsal region. There were no red striæ on the skin, but 3 weeks later one appeared on the abdomen and after another 10 weeks there were several. The blood-pressure at this time varied between 155/80 and 175/90 mm. Hg.

She was regarded as an early case of Cushing's syndrome and admitted to the Royal Victoria Hospital, Belfast, on Jan. 6, 1956. In addition to the previous complaints she mentioned diarrhœa and swelling of the ankles, and said that her hair had become darker and had been falling out for 6 months. On questioning she said that her face had become fatter in the past few months and that she was a little short of breath on exertion.

On examination (see figure) the face was rounded, the cheek had a cyanosed flush, and there was moderate hair growth on the upper lip, sides of face, and chin. An acneiform rash was present over the limbs and abdomen and there were several purple striæ on the abdomen. There was marked thoracolumbar kyphosis and the blood-pressure was 170/100 mm. Hg. Dullness and decreased air entry were found at the base of the right lung. The liver was enlarged three finger breadths below the costal margin it felt hard but was neither nodular nor tender There was no ascites, and the clitoris was not enlarged

Investigations

In September, 1955, X ray films of the pituitary fossa and intravenous pyelography were normal, and there was normal density of the thoracic spine The 17 ketosteroid excretion was 5 6 mg in 24 hours, in December it was 1 8 mg

In January, 1956, the patient had heavy glycosuria but no ketonuria X-ray films of abdomen and excretion urography were normal, as were films of the skull and the rest of the skeleton Films of the chest showed a large rounded mass projecting from the hilum of the right lung and compressing the right main bronchus Tomograms and bronchoscopy (Mr H M Stevenson) suggested a bronchogenic cyst We assumed that this mass was responsible for the chest signs but had no other significance A barium meal revealed a small ulcer in the region of the pyloric antrum Presacral insufflation of oxygen and tomography showed adrenal shadows of normal size and shape The blood sugar was 153 mg per 100 ml *in the fasting state, and rose to 344 mg 2 hours after ingestion* of 50 g of glucose The peripheral blood picture was normal The serum potassium was 2 m eq per litre, and the serum bicarbonate 37 m eq The hypokalæmia was sufficient to produce T wave changes in the electrocardiogram Liver-function tests revealed an alkaline phosphatase of 23 King-Armstrong units and serum bilirubin of 1 3 mg per 100 ml, but the thymol turbidity and zinc sulphate flocculation tests were normal A 6 day corticotrophin stimulation test (Prunty 1956) gave a normal resting value and rise for 17-ketosteroids The resting level of 17 ketogenic steroid excretion was normal, but no rise occurred after corticotrophin

Finally, peritoneoscopy (R B W) showed that the liver was largely replaced by bluish nodules of tumour Biopsy showed these to be anaplastic carcinoma, the source of which could not be identified

Progress

In the month after admission a few purpuric spots appeared on the trunk and the diarrhœa subsided On the night of Feb 4, she suddenly developed acute dyspnœa and retrosternal pain There was bronchospasm and generalised moist sounds were heard throughout both lungs The temperature was 104 5 F and the pulse irregular, the rate varying from 120 to 160 per min A myocardial infarct seemed the probable explanation of what was thought to be acute left ventricular failure, but next morning her dyspnœa and bronchospasm had disappeared and an electrocardiogram yielded no evidence of infarction The purpuric rash on her abdomen became more profuse Her temperature remained at about 105°F for the next 2 weeks 2 days after this attack her diarrhœa returned, and it remained severe for 3 weeks She passed 7–10 watery stools daily without blood or mucus Ascites developed very rapidly over the next few days but then gradually subsided Her abdominal striæ became less marked

Urine taken 3 days after this attack contained 5 hydroxy indole acetic acid (5 H I A A) identified by paper chromatography (Prof D C Harrison) The amount was greater than normal but less than is usual with a functioning carcinoid tumour After intravenous injection of 10 ml of 10% alcohol another specimen of urine showed a slightly greater amount of 5 H I A A On questioning the patient again, we found that she had noticed flushing attacks for 2 months before admission These attacks involved her whole body, lasted about a minute and came on after meals During her stay in hospital however there were no attacks of flushing *These findings suggested the presence of a functioning carcinoid tumour* but there was no clinical evidence of pulmonary or tricuspid stenosis Cardiac catheterisation was attempted but was unsuccessful

She continued to have attacks of dyspnœa at night although never as severe as the first, but otherwise she seemed to be improving and getting stronger However she died on April 8 after a few hours coma

Post mortem Examination

A spherical tumour 4 cm *in diameter was found at the* hilum of the right lung *The* bronchus and pulmonary artery were in close relationship but were not involved On section the tumour was *unencapsulated and fleshy in consistence* There were a few hæmorrhagic areas No other tumour was found in the lungs

The liver was much enlarged and contained numerous metastatic tumour nodules (diameter 3 mm to 3 cm) many with hæmorrhages There were tumour deposits in the lymph nodes of the porta hepatis and the para aortic region

In spite of a careful search no tumour deposits were found elsewhere In the heart, no endocardial thickening was evident, and the valve cusps were everywhere thin The endocrine glands appeared normal

Microscopy —The tumour in the lung was a carcinoma. *The cells ranged from the rather small ovoid cell seen in the* so called oat cell carcinomas to more definite polyhedral epithelial cells with more copious cytoplasm In the liver these latter cell types formed the bulk of the metastases, and in some areas definite, though rudimentary, glands were found

Sections of the pituitary and adrenals showed no lesions Crooke's hyaline change was absent in the basophils of the anterior lobe

Discussion

This case has two features of interest first, the co existence of Cushing's syndrome and bronchial carcinoma, and secondly, the presence of symptoms and signs suggesting a malignant carcinoid tumour

Only three cases of Cushing's syndrome associated with bronchial carcinoma have been reported previously (Brown 1928, *one case*, Thorne *1952, two cases)* In all of these the tumour was an oat cell carcinoma The pituitary was normal in one, enlarged in one, and the site of metastases in the third The adrenal cortices were normal in one and hyperplastic in two The livers of *two were extensively involved by metastases, and* that of the third showed central congestion and necrosis of the lobules

In our patient, as in Thorne's two cases, the liver was extensively invaded However, the brain, pituitary, and adrenals were normal This was an unexpected finding since in all the reported cases of Cushing's syndrome associated with carcinoma of the thymus or pancreas, and in two of the three described above with carcinoma of the bronchus, the adrenal glands were hyperplastic In the absence of adrenal hyperplasia the features of Cushing's syndrome in our patient are difficult to explain They might be attributed to failure of a heavily infiltrated liver *to inactivate* the adrenal cortical hormones, but if this were so, one would expect to see Cushing's syndrome more often in severe liver disease Moreover, the patient described by Brown had all the features of Cushing's syndrome but no metastatic involvement of the liver by the bronchial carcinoma There is no evidence that bronchial carcinomas are hormonally active, although Jepson (1956) has reported a case without features of *Cushing's syndrome in which the 17 ketogenic* steroid excretion was extremely high

In our patient, a few weeks before her death, the abdominal striæ became less prominent and the purpura and acneiform skin rash disappeared The case may therefore have been one of "transient Cushing's syndrome" (Zondek 1923), resulting from hypothalamic dysfunction (Zondek and Leszynsky 1956) A raised *intracranial pressure may be associated with* Cushing's syndrome, as in cases of meningioma in the region of the cervical cord (Heimbecker 1944) or cerebellar astrocytoma (Crispell and Parson 1952) The syndrome may disappear after the intracranial hypertension has been relieved The prolonged hyperpyrexia in our patient was another feature which might have been caused by hypothalamic dysfunction There is, however, no direct *evidence for this hypothesis*

The syndrome associated with malignant carcinoid tumour (argentaffinoma)—namely, flushing attacks diarrhœa asthma right sided valvular heart *lesions, and* hepatomegaly—is becoming well known, but cases exhibiting some or all of these features have been reported with carcinoma of various organs in the absence of a carcinoid tumour (Arnett and Long 1931, Cassidy

1931, 1934, Weber 1943, Rosenbaum et al 1953) However, carcinoid tumours are often associated with carcinoma in other parts of the body (Pearson and Fitzgerald 1949, McKusick 1956), and a carcinoid may have been overlooked in some of the patients with symptoms suggestive of its presence In our case a careful search was made at necropsy, but no carcinoid tumour was found

Estimation of 5-HIAA (a metabolite of 5-hydroxytryptamine) in the urine is now generally regarded as the most useful test for the presence of a carcinoid tumour and is thought to be specific Two cases of carcinoma, however, have been reported (one of the breast and one of the larynx) (Clerc Bory et al 1954) in which urinary chromatograms showed abnormally large amounts of 5HIAA It was not stated whether the livers were involved by tumour or not In a small series of cases of gastro-intestinal carcinoma with liver metastases (Snow et al 1955), a slightly raised excretion of 5-HIAA was reported, but the levels were much lower than those found in cases of malignant carcinoid by the same authors In another series of cases of carcinoma with metastases in the liver the urinary excretion of 5HIAA was normal (Haverback et al 1956)

In our patient, a slight excess of 5HIAA was found in the urine The liver was extensively infiltrated by metastases from a bronchial carcinoma, but no carcinoid tumour was discovered We conclude therefore that increased urinary excretion of 5-HIAA may occur with malignant tumours other than carcinoid

Summary

The case is reported of a woman of 55 with a carcinoma of the bronchus She presented the clinical features of transient Cushing's syndrome and had some symptoms suggestive of a carcinoid tumour There was a slight excess of 5HIAA in the urine, but a carcinoid tumour was not found at necropsy

We are grateful to Prof J H Biggart for his advice on the pathological findings, to Prof D C Harrison for the estimation of 5HIAA, to Mr H M Stevenson for the bronchoscopy, and to Mr R G Wood for the photograph

ADDENDUM

Since this article was submitted, Boyland et al (1956) have reported the detection of small amounts of 5HIAA in the urine of patients with carcinoma of bronchus and other sites, following the ingestion of 2 g of *l* tryptophan In these patients significant amounts of 5HIAA were not apparently found unless tryptophan had been ingested, although this is not definitely stated in every case

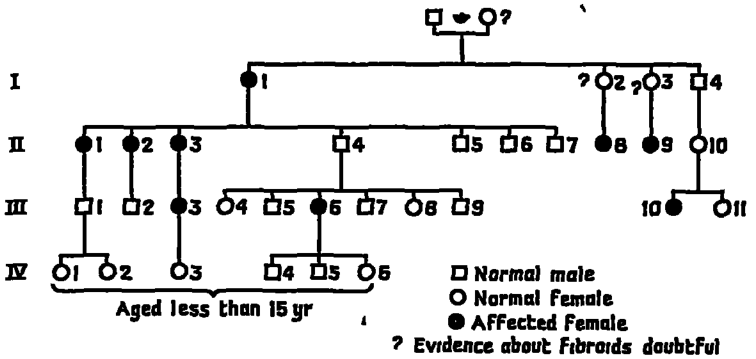
UTERINE MYOMA AS A HEREDITARY DISEASE

L E Wear
M B Leeds, D C H
GENERAL PRACTITIONER, CREWKERNE, SOMERSET

Uterine fibromatosis is not usually considered to be hereditary, but the occurrence of uterine fibroids in more than one member of a family has occasionally been noticed



Pedigree

Lockyer (1918) stated "It is certainly striking how fibroids run in families A patient of my own is one of five sisters, four of whom have had uterine myoma, and the fifth refuses investigation but is thought to be similarly afflicted"

Lagrona Weill-Hallé (1950) described two sisters, aged 19 and 22, with identical clinical features due to multiple small intramural uterine fibroids No family history was given

All the affected members of the family described here that I have managed to talk to had large uterine fibroids which produced a palpable abdominal tumour but no abnormality of the menstrual cycle They remained undiscovered until either they complicated a pregnancy or the abdomen was examined for some other reason

The Family

Generation IV (see figure) are all aged less than 15 and are excluded from the present survey At least 9 of the 15 females in generations I–III have had uterine fibroids I have talked to 5 adult members of the family independently, and all of these named the same relations as having had uterine fibroids, I have personally attended 3 of these patients, and 2 other cases were confirmed by the patient's own doctor

A typical case is that of III 3

> During a routine examination while she was in bed with influenza in March, 1956, a firm abdominal swelling extending up to the umbilicus was palpated That this was caused by several uterine fibroids was confirmed on bimanual examination The menses were regular and normal in amount At operation in August 1956, one large intramural fibroid and two medium sized subserous fibroids were found, and subtotal hysterectomy was done

Discussion

I 1 in the first generation had 7 children before undergoing a hysterectomy at the age of 44 This is an unusual number for a diseased uterus to bear Usually there are no, or only 1 or 2, children of a mother with uterine fibroids as in generation II This fact makes the disease self limiting by reducing the number of progeny

Uterine fibroids are rarely discovered before the fourth or fifth decade of life and even then may go unnoticed and symptomless It is therefore difficult to piece together a full hereditary picture, some with fibroids may be missed, particularly if they are unmarried or childless

From the family tree it looks as if the condition may be transmitted through males as well as females II 4, a man, has a daughter (III 6) with fibroids This might explain the occurrence of uterine fibroids in daughters of fibroid-free mothers and in women with no apparent family history of uterine fibroids at all

The presence of uterine myomas in three generations strongly suggests a dominant mendelian inheritance of a sex-limited type, the condition being confined to females There may be an instance here of the skipping of a generation, because II 10, herself apparently normal, has transmitted the gene from her father, I 4, to her daughter, III 10

A sine qua non of dominant genetic inheritance is the presence of the genetic trait in one or other parent, but, in a condition necessarily limited to females such as this, it appears to be possible to have normal parents with an affected daughter when the gene is transmitted through the male

There was no consanguinity

Summary

A family is described in which there is a high incidence of uterine myomas

The condition appears to be due to a dominant gene transmitted both by men and women, but of necessity expressed only in the latter

My thanks are due to Dr J A Fraser Roberts for his valuable comments on this pedigree

Preliminary Communication

THE ELECTROCARDIOGRAM AFTER EXERCISE IN THE DETECTION OF LATENT CORONARY-ARTERY DISEASE IN R A F PERSONNEL

THE early and accurate diagnosis of coronary-artery disease, with all that it implies, is particularly important in pilots and aircrew However, it is well known that in many patients suffering from angina pectoris the diagnosis has to be made on the history alone without support from physical examination or the resting electrocardiogram (E C G) Thus, approximately a third to a half of patients with angina pectoris due to coronary-artery disease have normal resting E C G s, if those who have hypertension, or have had prolonged attacks of chest pain are excluded, the figure is higher [1 2] The E C G after exercise has been used as an aid in the diagnosis of suspicious chest pain for more than twenty years with varying efficacy and safety [3] In this study the technique and criteria of Wood and his collaborators [1] have been followed, since their results seem to correlate best with clinical findings

This work was undertaken (*a*) to delineate further the normal electrocardiographic response to exercise, and (*b*) to investigate the possibilities of the effort test in the diagnosis of ischæmic heart disease before the development of symptoms Although Wood's experience with his control series [1] suggested that the effort test might be put to this purpose, no report of such a study is known to have been published

MATERIAL

This consisted of 540 healthy male R A F personnel between the ages of 19 and 54 The sample over the age of 40 was obtained in a slightly different way to that under the age of 40 It contained for example, fewer officers than the younger group It is hoped to eliminate any possible errors due to this difference in sampling in a further study A preliminary interrogation, physical examination, chest radiograph, and resting E C G (I, II, III, IIIR, aVR, aVL, aVF, V_{1-6}) were done in each case on the day of the effort test, and any subject with symptoms or signs of disease or an abnormal resting E C G was excluded The interrogation was directed particularly at excluding those with any suspicion of cardiac pain

METHOD

The effort test consisted in twice running down and up a staircase of 66 steps, each 10 in high, the subject choosing his own pace * All men over the age of 50, and 47 men between 40 and 50, performed a single trip of 66 steps The time taken to complete the test was recorded by stop-watch in each case, so that the effect of rate of exertion could be studied Leads I, II, III V_4 V_5, and V_6, were recorded 1½ min, 3 min, and 6 min after the completion of exercise A Philips direct writing electrocardiograph ('Cardioluxe') was used throughout

RESULTS

None of the subjects experienced chest pain during or after exertion 473 of the post exercise E C G s were normal (group A) The remainder (67 cases) showed (1) flat or sagging depression of the RS–T segment 0 5 mm or more below the level of PQ with deformity or inversion of the T wave (subsequently referred to as "organic type" RS–T depression), or (2) biphasic, isoelectric, or inverted T waves without RS–T depression (subsequently referred to as isolated T-wave changes) Cases in which these changes occurred in lead III only were classified with group A So were cases in which a depressed RS–T junction sloped up to a normal T wave [1] 55 of these 67 cases were studied on a second occasion after the lapse of weeks or months in 44 the changes noted on the first occasion were confirmed, in 11 cases the second post exercise E C G was normal, and in a further 3 cases the changes on both occasions were doubtful (these were classified separately in group C) (table I) The anomalies in the 53 cases finally classified in group B are set out according to age in table II To exclude anæmia as a possible cause of the changes in groups B and C, a hæmoglobin estimation was done in every case, no evidence of anæmia was found

TABLE I—ABNORMAL E C G S

Age (years)	No of cases	Group B	Group C % (doubtful or inconsistent anomalies)
19–39	300	16 (*5 3%*)	4 (*1 3%*)
40–54	240	37 (*15 4%*)	10 (*4 2%*)

GROUP B AND AGE

The E C G s classified in columns 3, 4, and 5 (table II) are "abnormal" according to Wood's criteria Those in columns 2 and 6 are "borderline" Columns 3 and 4 represent cases with changes identical with those previously described as due to myocardial ischæmia The significance of isolated T wave changes without RS–T depression is less certain [4], many of the tracings in this group were similar to those illustrated in Wasserburger's study on the effect of hyperventilation in patients with anxiety [5] It is interesting that organic type RS–T depression is commoner at the older than the younger ages (as I have

[5] Wasserburger R H Lorenz T H *Amer Heart J* 1956 51 666

TABLE II—GROUP B SUBDIVIDED ACCORDING TO TYPE OF ANOMALY OF RS–T COMPLEX

Age (years)	(1) No of cases	(2) 0 5 mm RS–T depression with deformity of T not amounting to inversion	(3) 0 5 mm of RS–T depression with inversion of T	(4) 1 0 mm or more RS–T depression with deformity or inversion of T	(5) Diphasic, isoelectric, or inverted T waves without RS–T depression	(6) RS–T depression with deformity of T restricted to leads II and III
19–39	300	1 (*0 3%*)	2 (*0 7%*)	5 (*1 7%*)	7 (*2 3%*)	1 (*0 3%*)
40–54	240	11 (*4 6%*)	3 (*1 2%*)	15 (*6 2%*)	4 (*1 7%*)	4 (*1 7%*)

said, further work is being carried out to determine whether this difference is due to age or to the fact that the two samples of men were derived in different ways) On the other hand, there is no such increase in isolated T-wave anomalies over the age of 40

GROUP B AND OTHER FACTORS

There was no significant difference between group A on the one hand, and groups B and C on the other, in respect of (1) the resting heart-rate, (2) the heart-rate 1½ min after exercise, (3) the rate of completion of the exercise test, and (4) degree of athletic training in the three months before the exercise test

FAMILY HISTORY

In 529 cases the family history was recorded before the effort test was performed In 12 cases, all in group A, the family history is unknown, in 6 the man had been adopted by foster parents and did not know the fate of his family The remainder were the first 6 consecutive cases in the series in which, owing to an oversight, no details were recorded In table III column 2 shows the number of families in groups A, B, and C in which at least 1 relative (father, mother, brother, or sister) had suffered from coronary thrombosis or angina pectoris or had "dropped dead" In columns 3 and 6 these two groups are listed separately It will be seen that the incidence of positive family histories is consistently higher in group B than in group A The total number of sibs per family in the two groups is comparable Within group B 7 of the positive family histories occurred in the 37 cases with RS–T depression other than in leads II and III alone (mean age 42 3) and 1 positive family history in the 11 cases with isolated T-wave changes (mean age 35 3)

TABLE III—FAMILY HISTORY

Group	Age (years)	(1) Total no of family histories traced	(2) Positive family histories	(3) Coronary thrombosis or A P (alive or dead)	(4) Coronary thrombosis or A P (alive)	(5) Coronary thrombosis or A P (dead)	(6) Sudden death

		53	9	4	0	4	5
C	19–39 40–54	4 10	1 1	0 1	0 0	0 1	1 0
		14	2	1	0	1	1

PROVISIONAL CONCLUSIONS

In a highly selected series of 540 clinically healthy males so far studied, 53 show a deviation from the usual electrocardiographic response to exercise In 11 of these the anomaly consists of isolated T-wave changes without RS–T depression If 5 cases in which the RS–T depression is restricted to leads II and III are excluded, there remain 37 cases with "organic type" RS–T depression identical in pattern with that found in myocardial ischæmia, in 20 of these the RS–T depression is 1 mm or more Preliminary analysis suggests (1) that "organic-type" RS–T depression is commoner over the age of 40 (this does not extend to cases with isolated T-wave anomalies), (2) that coronary occlusion, angina pectoris, and sudden death may be commoner in the blood relatives of subjects with an abnormal E C G after exercise than in the relatives of those with normal tracings The relationship of the anomalies in the post exercise tracings of group B to latent coronary-artery disease remains to be proved but it is felt that the evidence is sufficiently suggestive to make further study and an extended follow-up worth while

CHOLESTEROL AND LIPOPROTEIN ESTIMATIONS

By courtesy of Prof Sir Charles Dodds blood studies have been carried out by Dr G L Mills at the Courtauld Institute of Biochemistry in 45 subjects in group A and 33 in group B The results have not yet been analysed

I wish to thank Air Marshal Sir James Kilpatrick director general of medical services, R.A.F, for permission to publish this report, Air Commodore C A Rumball consultant in medicine, R.A F, and Dr D Evan Bedford, civilian consultant in cardiology, R A F, for help and guidance, Prof A Bradford Hill, F.R S, for statistical advice, and the officers and airmen of the R A F for their cheerful coöperation

Medical Societies

HEBERDEN SOCIETY

THE annual meeting of this society was held in London on Dec 14 and 15, under the presidency of Dr ERNEST FLETCHER There follows a short report of the scientific proceedings

SUBLUXATION OF THE NECK IN ANKYLOSING SPONDYLITIS

Dr J SHARP and Mr D W PURSER (Manchester) called attention to the risk of spontaneous subluxation of the atlas on the axis in patients with ankylosing spondylitis Their first patient died with a spastic tetraplegia, and a photograph at necropsy showed vividly the protrusion of the odontoid process into the spinal canal when the head was flexed on the neck, with consequent pinching of the cervical spinal cord Since then they had recognised 9 further cases of this subluxation during life and certain features emerged The patients were all males, ages ranging from 31 to 64, in all of them the spondylitis was severe and of long duration and there was little or no residual normal spinal movement Most of them had severe lumbodorsal flexion deformities In 1 patient a prominent presenting symptom was the increasing difficulty of shaving under the chin because of the falling forward of his neck Later he developed twitching and weakness of his limb muscles, with three episodes of complete paralysis which followed attempts at bending down He needed treatment in an iron lung at one stage, but eventually made a complete recovery when the cause was recognised and the neck fixed in extension It was important to note that this patient and 4 others had minor cervical subluxations below the atlanto occipital joint Radiologically the latter were less easy to miss on ordinary cervical films, and might be blamed for the symptoms The atlanto axial subluxations, on the other hand, were best demonstrated by taking lateral films in flexion and extension, and were clearly the cause of the neurological symptoms Other patients presented with "painful instability" of the neck One, for example, with largely "burnt out" spondylitis of twenty years' duration, began to have pain in his neck which forced him to support his chin in his hands while riding in a car Some presented with severe pain in the neck or occipital region

Dr Sharp and Mr Purser now regarded the presence of neurological changes as an absolute indication for operative cervical fusion 6 patients who have so far been treated in this way have lost their symptoms Signs of cord damage, if any, have proved almost wholly reversible They suspected that this complication of ankylosing spondylitis was more common than was generally thought, and urged its early recognition, in order to relieve pain, to protect the cervical cord before irreversible changes occur, to ensure that such necks are not subjected to manipulation, and to spare the patient from X-ray treatment that might be given if the neck pain was assumed to be due to a recurrence of activity of the spondylitis

UNEXPECTEDLY RAISED SEDIMENTATION RATES

Dr B M Ansell and Dr E G L Bywaters (Postgraduate Medical School, London) reported that out of several hundred routine sedimentation-rates done on outpatients when first seen at a rheumatism clinic, there were 51, in a three year period, where the result was unexpectedly high and did not seem to correlate with the clinical findings In 31 of these this rate was elevated on two or more occasions, and these 31 patients had been recalled for extensive further investigation Most of the patients in whom a diagnosis could eventually be made proved to have rheumatoid arthritis, although in some the progression of the disease was unusual One, for example, had presented with no more than persistent œdema of the feet and high E S R Later she had attacks corresponding to palindromic rheumatism After two years, arthritis became constant, erosions appeared in the joint radiographs, and the differential agglutination test (D A T) became positive Another patient with mild articular symptoms and asthma developed myelomatosis In another the raised E S R was due to circulating cold agglutinins In only 1 was the raised E S R explained as the result of unrecognised malignant deposits Finally, in a few patients no cause was found, and in some of these the sedimentation rate was still raised

SACRO ILIAC JOINTS IN ANKYLOSING SPONDYLITIS

Dr J Forestier (Aix les Bains) reviewed his cases of ankylosing spondylitis in the light of Gilbert Scott's hypothesis that the disease was one of inevitable progression ceasing only when the sacro iliac joints were fused He could not support this, and found that the disease might arrest at any stage, or alternatively active spinal disease could be present when the sacro iliac joints were fused

DIURNAL VARIATION IN HAND GRIP

Dr V Wright (Leeds) had studied the daily variation in the strength of hand grip There was a diurnal rhythm in normal subjects the grip being weakest about 6 A M, rising sharply to a maximum at about 9 A M, after which it stayed more or less constant until a slow decline set in about 2 P M This was not related to blood sugar levels but there was parallel variation in the body temperature and inverse variation in the count of circulating eosinophils, and all three probably reflected the normal rhythm of intrinsic adrenocortical activity It took 18 days, however, before the administration of corticotrophin to a normal subject abolished this daily variation and the normal pattern was soon restored when the dose was reduced Patients with rheumatoid arthritis (unless their hands were severely deformed) also showed this variation of grip, but (in contrast with the findings in normal subjects) the variation was quickly and strikingly abolished when effective doses of corticotrophin were given Wax baths to the hands and injections of pitressin had no influence on the diurnal variation

SODIUM-RETAINING PROPERTIES OF CORTISONE AND PREDNISONE

Dr Ansell had used the technique of giving by mouth isotope sodium (^{22}Na) chloride to measure total body water and the turnover rate of body sodium Readings were made with the subject in a total body counter, and the radioactivity of a single specimen of urine was measured Several experiments confirmed the validity of the method, after which it was shown that cortisone caused a delay in the turnover of body sodium in patients with rheumatoid arthritis Prednisone (deltacortisone) had no such effect in equivalent doses, indeed the sodium-retaining action of cortisone was abolished when prednisone was given concurrently

PHYSIOTHERAPY IN THE RHEUMATIC DISEASES

Dr J S Lawrence (Manchester) gave details of the results of physical therapy in miners attending a diagnostic and rehabilitation clinic Seventeen different treatments were allotted according to a rota and were continued until the patients recovered or ceased to improve He measured his results in terms of the palliation of symptoms, the disappearance of abnormal physical signs, and the time it took for the patient to return to work, and he had analysed them according to the underlying disease process Only in osteoarthritis and degenerative disc disease did treatment materially improve the disability, and of the treatments given only infra red irradiation and saline or citrate ionisation gave seemingly significant advantage over placebo treatments Rheumatoid-arthritis patients were, if anything, made worse by prescribing active or passive movements

LABORATORY STUDIES

Dr H J Gibson and Mr N R Ling (Bath) had investigated the streptococcal hæmagglutination test The antigen in this test was a combination of a non specific polysaccharide (which could be extracted from filtrates of cultures of many gram-positive organisms, including streptococci) and human red cells The antibody was of widespread distribution, was present at birth, disappearing at six months, then reappearing with increasing age It was present in all body fluids, it fixed complement, and it caused the agglutination of the treated red cells The apparent serum titre of this antibody was often outstandingly high in rheumatoid arthritis, but did not always correlate with the differential agglutination test (D A T) They showed that the titre in the streptococcal agglutination test depended on two factors, one of which could be absorbed from the serum and which they thought was the antibody The other factor was an augmentor which was probably responsible for the high titres in rheumatoid arthritis, and it seemed likely that this augmentor was allied to if not identical with the substance responsible for positive agglutination in the D A T

Dr Baruch Blumberg and Dr A G Ogston (Oxford) had studied the effect of crystalline papain on the hyaluronic acid protein complex which could be isolated from ox synovial fluid by ultrafiltration The protein was essential to the physical properties of the complex, and could be almost entirely removed by this enzyme The solution of this complex exhibits an anomalous viscosity which is lost after digestion Trypsin and chymotrypsin were ineffective, and various control experiments showed that the action was not due to the contamination of the enzyme with lysozyme It was possible from the viscosity measurements to calculate the molecular weight and size of the digested hyaluronic acid

The Heberden Oration

In the 1956 Heberden Oration, Prof R E TUNBRIDGE (Leeds) discussed the connective-tissue system The three essential elements of the system were cells, fibres, and ground substance Recent work from the King's College group had shown that there were probably three types of fibroblast or fibrocyte Characteristic of these were intracytoplasmic granules which stained metachromatically, contained about 30% of protein, and were rich in hexosamine The granules were either the immediate precursors of collagen fibril formation or were in some other way intimately related to it The function of the mast cells was still not known with certainty Probably they stored heparin, and in addition they might be concerned with the synthesis of hyaluronic acid and also with local histamine release There was at present no acceptable evidence for an elastoblast Under the light microscope three types of fibre had been differentiated—collagen, elastin, and reticulin But there were fallacies in the histochemical techniques, since altered collagen might stain like elastin, and reticulin, which was differentiated mainly on its silver staining, could be shown under the electron microscope to contain collagen fibrils

A characteristic feature of collagen was its periodic banded structure with 640 Å spacing At least 10 sub bands had been demonstrated Collagens from different animal sources might show different periodicity Fœtal collagen might occur in sheets rather than fibres (its periodicity was still apparent), and Keech had shown that the fibril width increased with age Indeed there was a characteristic fibril width for different tissues Other differences in collagen fibrils could be demonstrated by silver staining, which could either be a uniform surface coating of the fibril, as in scleral collagen, or internal staining of certain of the bands—a feature of ageing collagen Wyckoff had shown that the fibrils were tubular Collagen contained more lysine, hydroxylysine, and arginine than elastin, which was richer in valine and leucine There was evidence that the small amount of carbohydrate in collagen was not just a contaminant Gross had illustrated the interesting variations in the structures formed when collagen was precipitated from solution in vitro

The concept of "collagen disease" as originally put forward by Klemperer had acquired a meaning that he never intended Primary disorders of the fibrous structure of the body were rare They included pseudoxanthoma elasticum, a disease which was uncommon before the second decade and which showed itself as redundant thickened skin and a tendency to calcification of the small blood vessels It was the result of an excess of altered collagen which stained like elastin under the light microscope In the Ehlers Danlos syndrome, on the other hand, occurring in infancy and childhood, the electron microscope confirmed that there was a true excess of elastin There was a naturally occurring inhibitor to the enzyme, elastase, which was present in increased amounts in this syndrome It was clear that rheumatoid arthritis was not a collagen disease in the literal sense and it was unlikely that lupus erythematosus could be so classified

Reviews of Books

Industrial Medicine and Hygiene

E R A MEREWETHER, CB, OBE, MD, FRCP, barrister at Law, H M senior medical inspector of factories, Ministry of Labour and National Service London Butterworth 1954–56 3 vols £10 10s. the set

THE need for an authoritative and comprehensive book on this rapidly developing subject has been felt for several years The subject being a composite one, Dr Merewether's task has been difficult and he has called on a wide variety of experts Such a team produces its own problems The editor must on the one hand allow contributors to conserve their individuality, while on the other he must persuade them to conform to an over-all pattern Perhaps in this instance the editor has not been ruthless enough, for the work, though good in parts, does not conform to a clear plan

The first volume which appeared in 1954, is the least attractive of the three It contains a few good sections, but much of it is uninspiring The section on the law provides an easy source of reference but it is a pity that no consideration is given to the history of our factory legislation—an enthralling story without which it is difficult for the reader to understand the present position There is a good section on the use of statistical methods in the occupational field and another on reablement and resettlement of disabled workers

The second volume, which also appeared in 1954 brings together much valuable material The subjects cover a wide range—from industrial dermatology to electric shock and from occupational psychology to the effects of ionising radiations There is a good account of compressed-air illness, though its importance could hardly justify the 46 pages allotted to it The section on industrial skin disease is concise and practical while the chapters on heating and ventilation and on lighting are readable expositions of highly technical subjects

The third volume, which has only recently appeared, is probably the best It deals with the dust diseases and with industrial carcinogens and toxicology Both these sections are of high quality and offer comprehensive summaries of present day thought and practice This volume is particularly well documented A vast amount of practical information about the fibrotic pneumoconioses is crammed into the first 120 pages while the following section provides an excellent and well balanced account of the diseases due to vegetable dusts The final section of this volume deals with industrial toxicology The writer has confined himself to an examination of the "mechanism of action of some industrial poisons" The result is stimulating, even though some may experience difficulty in following the biochemistry This method leads to certain practical difficulties—for instance some 25 pages are devoted to the anticholinesterases but benzene is not mentioned This might be excused in such an imaginative contribution if the foreword did not claim that "the approach to each subject is dogmatic and practical so as to meet the needs of all

In each section the references cover a wide range There are notable omissions in the text—for instance, one looks in vain for a section on accidents where some of the present day ideas on this important subject are brought together and in the chapter on electric shock the medical side is virtually ignored Some overlapping is inevitable and even beneficial in a book of this sort but occasionally it becomes annoying

These faults can no doubt be corrected in the next edition Dr Merewether has provided much that is of great value in these volumes, which are to be welcomed as an important pioneering effort Copies of this work should certainly be held in all medical and technical libraries and all health departments in industry

Family Medical Costs and Voluntary Health Insurance

A Nationwide Survey ODIN W ANDERSON, PH D, Health Information Foundation, JACOB J FELDMAN, National Opinion Research Centre New York and London McGraw Hill 1956 Pp 251 40s

TWENTY-FIVE years ago voluntary health insurance had hardly begun in the U S A, and the principle of health insurance was still being hotly debated In 1933 I S Falk, Margaret C Klem, and Nathan Sinai published the first nation-wide survey of the incidence of illness and the costs of medical care Since that time health insurance has greatly increased, and today about a hundred million people are covered in one way or another, but the most comprehensive health-insurance schemes now available hardly cover half of the cost of all services in a year Since 1950 private insurance has been gaining over Blue Cross, which in turn is ahead of Blue Shield Group-practice prepayment plans cover less than 5% of the population, but are gaining slowly

These and many other facts are well brought out in this book, which describes the first national survey of family medical costs undertaken since 1933 The authors conclude "the form that health insurance has taken and will take is a tenuous balance between the many elements that make up the complexities of personal health services - people, hospitals, physicians, insurance, and finance, interlaced with philosophies of government and private enterprise and with the level of public information and knowledge"

This readable book contains much information valuable to those concerned with administering and organising medical services

Principles and Methods of Sterilization

JOHN J PERKINS, M S, director of research, American Sterilizer Co, Erie, Pennsylvania Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1956 Pp 340 60s

It is clear from this book that the author's main interest is sterilisation by heat

The importance of gravity displacement of air and automatic air and condensate discharge is made clear, but the statement that these have been almost universal since 1933 is unfortunately not true in this country There are detailed instructions for operating autoclaves and ovens, but the value of some of these is limited because they refer to equipment made by a particular manufacturer The importance of regulating autoclaves on temperature rather than pressure readings is stressed throughout the book The advice on preparing and packing loads for sterilisation is excellent, going well beyond the usual vague instruction to "pack loosely" Methods for sterilising most articles in common hospital use are given, these are generally sound, though blankets are only briefly mentioned and boiling them, as recommended, is unnecessarily destructive The wisdom of exposing rubber gloves to 121°C (15 lb per square inch) for 20 minutes may be questioned, for this could increase the risk of punctures during use For the operating theatre the author prefers autoclaving to boiling surgical instruments, and he rightly criticises water sterilisers

In this country the book could be profitably read not only by those who use but also by those who choose the sterilising equipment for our hospitals and laboratories

Annual Review of Microbiology

Vol 10 Editor, CHARLES E CLIFTON, Stanford University Palo Alto, California Annual Reviews Inc 1956 Pp 426 $7 50

FOR 1956 the number of articles of medical interest is less than usual Indeed, the time has come when the publishers might consider regrouping the whole series Microbiology—the study of very small living things—may seem a logical division of knowledge, but smallness itself and similarity in experimental method are not by themselves a satisfying link The great majority of those who term themselves "microbiologists" are primarily interested either in some small department of the subject or in its application to medicine, agriculture, or industry Accordingly there can be very few who will read more than 10% of this volume with interest or even with reasonable understanding Medical bacteriology by itself (or with medical virology) would provide enough material for an annual review, or it might be combined advantageously with pathology (in the Old World sense of the word) Some articles in this volume are fit for the review of biochemistry and others for some botanical publication

The standard of the contributions is at least as high as in any previous year J B Enright's review of the part played by bats in the transmission of rabies is as complete as anyone could wish and makes a story worth reading The increased interest in the lower plants is reflected in five articles on fungi and algæ A W Downie and K R Dumbell contribute an article on the pox viruses which might be a model for some other contributors

---

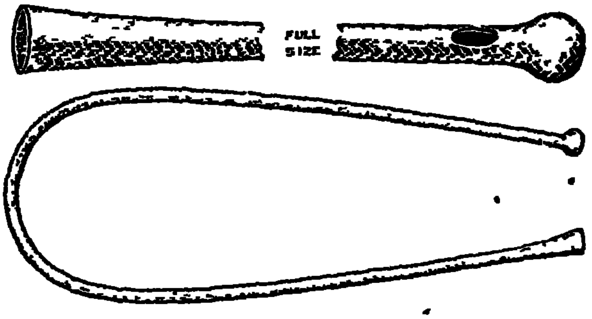
Surgery of the Hand (3rd ed Philadelphia Lippincott London Pitman 1956 Pp 1079 147s)—When this work by Dr Sterling Bunnell first appeared, in 1944, it was soon established as a classic Surgeons throughout the world will be grateful that Dr Bunnell has not been content to rest on his oars, the new edition is abreast with the times in matters of antibiotics, plastic repairs, and reconstructions—indeed in all aspects of hand surgery reflecting recent developments—and in most of these the author himself has been a pioneer

New Inventions

A GASTRIC CATHETER

THIS simple appliance has been found to have a range of usefulness out of all proportion to its modest cost The catheter is of gum-elastic It is 68 5 cm (27 in) long and has a diameter of 0 5 cm At the leading end there is a ball or olive tip 1 cm wide, just proximal to which is the aperture for aspiration

Owing to its large blunt end and semi-flexible material, the catheter may be passed with safety down the gullet of an anæsthetised patient It is then invaluable for aspirating the stomach, either when the patient has failed to swallow a tube before operation, or when the tube he swallowed has coiled up and has not entered the stomach



During a gastric operation the catheter may be passed by the anæsthetist so that its olive tip appears at the anastomosis It can then be used to draw into position an ordinary gastric tube, after this has been tied to the end of the catheter by the surgeon

The catheter is also readily passed on a *conscious* patient, particularly if he first sucks an amethocaine ('Decicain') tablet to anæsthetise the pharynx, and it has proved very useful when a patient urgently requires gastric aspiration but cannot swallow an ordinary soft tube

The catheter is useful for aspirating the gullet of a patient with an obstructing œsophageal lesion before operation The non-collapsible nature of the tube is an asset when aspirating, as is the fact that the ball end holds the aperture away from the mucosa

Again, I pass the gastric catheter before a gastroscopy, to empty the stomach This serves as a sort of trial run for the patient, and safely tests the patency of the route to be followed by the gastroscope It also does away with the need for the unpleasant preliminary swallowing of a soft tube for aspiration—a procedure which often leaves the patient keyed up and apprehensive and in no state to undergo gastroscopy I pass the catheter again after the examination to release the air from the stomach

The gastric catheters have been made for me by the Genito Urinary Manufacturing Co, Ltd, 28A, Devonshire Street, London, W 1 at a cost of 15s 9d each They can be made radio opaque for an extra 3s 6d

THE LANCET

LONDON SATURDAY, JAN 5, 1957

Return to Planning

1957, we are told, should be a year of reappraisal, in which the nations consider whether their policies need modification to fit the facts revealed by recent crises For the medical profession in this country a similar review of ends and means may be desirable, since the year opens with a conflict that could go deep From the beginning of the National Health Service there have been many who doubted whether the State should be allowed to assume—however indirectly—responsibility for so much medical work and thereby for the livelihood and ' terms of service of so many doctors whose professional independence must be preserved These doubts could be countered only by supposing that in their share of this new social task a British Government could be expected, in the long run, to act reasonably By handling too cleverly the profession s case for higher remuneration, the Health Ministers have again made this supposition seem rash Admittedly the case has been presented to them mainly in legal terms, but in nine months they have found no opportunity to explain their negative attitude in a way that might be understood and respected by doctors, and if they continue to look like arbitrary employers rather than like friendly partners in a great enterprise they will certainly revive the ashes of controversy which have been smouldering since 1948 On the other hand, in the absence of heavy insurance, a conflagration is seldom beneficial unless carefully localised and anyone who thinks of urging doctors to leave the service, or to demand a new model, should be sure just how far he wants to go Believing that discussion of objectives could be useful at this juncture, we shall be glad in the next few months to publish constructive contributions on the service and one such appears in this issue under the heading of ' Reconstruction '

Certain weaknesses of the N H S are inherent, and must be accepted as the defects of its virtues Essentially the service is a device for enabling everybody to get medical care without paying for it directly, and it was welcome for three main reasons (1) because much disability can be prevented if people can get sound attention whenever they need it (2) because many families found the cost of illness more damaging than the illness itself, and (3) because discontinuance of charges by doctor to patient should allow everyday medicine to resume an older tradition of service—derived from the temple priest rather than the man of business But every fresh advantage carries its own disadvantage as soon as access to free medical care is recognised as a right somebody must see that any citizen can get it and even in a temple somebody must see that the priests are fed Though the primary aim of the N H S is to enable people to get, without paying the same kind of care as they would get if they paid, and though this care is given by the same doctors and the same institutions (who remain highly responsible for its quality), a certain amount of organisation is inevitable because private arrangements must give place to public arrangements Moreover if patients are not to pay at least a large proportion of what their illness costs, most of the money for the service must be found from some kind of taxation, and this means that what is spent on the service, and on those who work in it, must ultimately be controlled by the Chancellor of the Exchequer and by Parliament—i e, by statesmen or politicians Which is not to say that the service need be so rudely exposed to political vicissitudes as it has been to date, or that, even in England, consistency should forever be at the mercy of expediency In peace, as in war, the first seven years are always the worst

Also inherent in the service is the patient s right to medical care without payment—the absence of a financial fence between him and his doctor This, too, has its disadvantages When the patient had no rights beyond what he paid for, his expectations were limited, and the doctor very often had the great professional and human satisfaction of exceeding them—even to the extent of waiving his fees—for which the patient was grateful But there is less satisfaction in helping people who take everything for granted, and the pleasures of practice are definitely reduced by the occasional patient who believes that his insurance contributions have bought anything his doctor can do for him Perhaps chiefly for this reason, there is now a move towards replacing the annual capitation fee by the New Zealand system in which the doctor charges for each item of service and the patient recovers part or all of this charge by taking a certificate to the post-office But the number of services rendered is by no means necessarily a good index of the value of a doctor s work, and before any big change is made in the N H S arrangements the profession ought to make up its mind more clearly on how far it wants practitioners to remain in competition with one another The capitation system allows and encourages competition for patients the New Zealand system would restore competition, in addition, for fees while a salaried service would abolish financial competition altogether Each has its undesired consequences, and instead of abandoning the capitation fee, of which we now have considerable experience, it might be better to continue the process of making it more flexible, adjusting it not only according to the number of people on the doctor s list but also according to the number who are old, young disabled, or otherwise at special risk Another possibility would be to give the family doctor more chances of earning supplementary fees—for instance by undertaking the daily care, at home, of patients who could not otherwise be discharged from hospital And perhaps there is room in general practice for some variant of merit awards, now confined to consultants[1] By itself, without modification or supplementation capitation is too crude a means of deciding how much a doctor has earned and if medicine is to become a temple, we must certainly get away from the rule by which a priest can get most to eat if he does as little as possible for as many as possible

This brings us to weaknesses which are not inherent in a free service but come of failure to plan it as a whole. This failure is almost praiseworthy in so far as it reflects a wish to delegate responsibility for the various parts of the service, and, even though it causes overlapping and untidiness, there is much to be said for leaving the hospital authorities, the executive councils, and the local authorities to do their own work in their own way. But a minimum condition for the success of a tripartite service is that the decision as to what work each part should regard as its own shall be taken by some integrating authority which can adjust the financial incentives accordingly. In the N.H.S. too many incentives have worked too long in favour of sending people to hospital when they could be treated more economically at home[1], and though the Ministry of Health has become keen to promote home care it has not yet created financial conditions in which practitioners and local authorities will be eager to relieve the burden on hospitals. Strongly though we believe in preserving the responsibility of individual doctors and the institutions in which they work, we think the service has suffered and is still suffering from lack of a coherent policy—from lack, indeed, of a central brain such as its advisory machinery was originally intended to provide. The crisis over remuneration is only the latest instance of failure to plan ahead; and if, after so many years of inflation, the Government really have not begun to consider its implications for professional people working in a national service, the least they can do, surely, is to ask a properly constituted committee to advise them on how the intentions of the Spens Committees should henceforward be fulfilled. Meanwhile we trust they will not be unwilling to consider, as a matter of urgency, the situation of those groups in the service—medical and other—whose incomes in 1950 were barely sufficient and are now reduced by about a quarter. Thinking particularly of senior registrars and senior hospital medical officers, whose professional situation has so long been debated without conclusion, we have to recognise the planning responsibilities of the profession as well as of the Ministry.

After the war this country had its fill of planning, and the word began to evoke a touch of nausea. But this reaction has gone too far; and the time has come, surely, when we should consider how the lessons of the first decade of the N.H.S. can be applied in the second. Looking at the biggest issues, we may hope that, before many years are past, the service will be largely removed from current politics by being accorded as of right a defined proportion of each year's national income; but on the purely professional level also there are important changes to be made—in reducing the rigidity of specialties, for example, and in achieving wiser relations between teaching and other hospitals by such methods as the one Professor PICKERING proposes in his final paragraph on p. 2. In urging examination of the service's faults, we are none the less proud of its successes—of the steady if unspectacular improvement of the hospitals, of the reforming ardour seen today in general practice, in the treatment of the mentally ill, and in the care of the old; and especially of this country's place in medical research and teaching. Just as people say that universities are nothing like as good as they were before the first world war, so they say that medicine has suffered gravely from the social revolution. But in some ways the universities, in their abundant new life, are better than ever; and so is medicine. Certainly it is incalculably more useful, which is what matters most to the patient.

The Decline of Acute Rheumatism

IN both Great Britain and the United States rheumatic fever is by no means as common as it was. In this country the number of patients admitted, for example, to the convalescent hospital for rheumatic fever in Birmingham, has fallen from 116 in 1938 to 44 in 1955.[1] In Baltimore the outpatient clinics are no longer crowded, there are empty beds in the convalescent homes, and all patients with rheumatic fever who require hospital treatment can be accommodated.[2] In San Francisco, the number of patients suffering their initial attack has fallen from 116 in 1945 to 20 in 1955.[3] Valvular heart-disease was about twice as common in young men examined for the United States Forces in the first world war as it was in the second[4], and a study of rheumatic fever in American school-children has shown a steady fall from about 4·5 first attacks per 1000 children in 1927 to 1·8 per 1000 in 1953.[5] HEWITT and STEWART[6] estimated that in England and Wales, in 1948–50, about 3900 children fell ill with a first attack of acute rheumatism each year—an attack rate of 0·69 per 1000. HITCHINS[7] has made a valuable study, covering the twenty years 1931–1950, of the records of the local rheumatism service of the city of Cardiff, basing his observations on those patients with acute rheumatism and associated carditis and those with actual rheumatic heart disease. During the twenty years there was a substantial fall in the "first attack" rate, which was most striking soon after 1930, and by 1950 the rate had fallen to a third of the level of the early '30s. A similar decline was noted in acute rheumatism without evidence of cardiac involvement.

There is also evidence that the mortality of rheumatic heart disease has decreased. Though KNOWELDEN[8] was unable to demonstrate any significant change in either men or women, he did detect a decline in mortality in children. In America there are a number of observations illustrating this fall in mortality over the past twenty years—an improvement varying from 70 to 80%.[4,9] The association of rheumatic fever with infection by hæmolytic streptococci has naturally suggested that changes in the character of the hæmolytic streptococcus and the progressive betterment of living conditions are the two factors most likely to be responsible for what has happened. But little is known about the epidemiology of streptococcal infections and even less about possible unrelated causes of rheumatic fever; and it is therefore hard to give any concise explanation. There is nothing to suggest that the hæmolytic streptococcus is, in fact, any less powerful a producer of rheumatic fever than it was, indeed, **Rammelkamp**[10] suggests that the proportion of streptococcal infections that lead to rheumatism remains relatively constant between 2% and 4%. As for the frequency of streptococcal infections, the only figures readily available are those for the incidence and mortality of scarlet fever. **Hitchens** drew attention to the close, although perhaps fortuitous, connection between the decline of rheumatic fever and that of scarlet fever, which has become steadily less common and less menacing from 1935 onwards. From their study of Sheffield, Bristol, Grimsby, and Lincoln, and the administrative county of Lincolnshire, **Hewitt** and **Stewart**[6] decided that poor housing and economic conditions per se played little part. **Hitchens**[7] came to the same conclusion, pointing out that the change took place in Cardiff before economic conditions improved. The incidence of rheumatic fever increases when the hæmolytic streptococcus has more opportunities to start infections, as it has among people living in overcrowded conditions—a point well brought out by a number of investigations in the American Armed Forces.[10] **Hewitt** and **Stewart** found that children of unskilled workers suffered from rheumatism far more commonly than did the children of professional and skilled workers, and they believed that different risks of infection were the most likely cause for the social gradient. **Rammelkamp** concluded that latitude, altitude, crowding, dampness, economic circumstances, and age all had their bearing on rheumatic fever simply because of their influence on streptococcal infections in general. **Hitchens**, however, made an important point in discussing the search for the cause of rheumatic fever's decline: the change should not be considered on its own, but in relation to the comparable decrease in the incidence and mortality in all infectious diseases quite apart from any recent advances in treatment. It seems unlikely that this general improvement can be attributed simply to alterations in the host-parasite relationship of a number of different organisms, and consequently there must be some associated economic factor still to be considered. **Hitchens** suggested that the decline was likely to be related more closely to such things as "an improving quality of maternal care rather than to a straightforward economic or physical factor", and that the increased use of antibiotics did not play a big part in the decrease in rheumatic fever, which had already began before antibiotics were introduced. Though this is undoubtedly true, **Robinson**[3] reports that the recurrence-rate in San Francisco remained relatively high despite fewer initial attacks, but after a preventive campaign and the provision of prophylactic drugs (either a small daily dose of sulphadiazine or penicillin or the monthly injection of a long-acting penicillin) the number of recurrences fell from a yearly average of 22 for 1949–53 to 5 for 1954–55.

9. Wolff, G. *J. Amer. med. Ass.* 1951, 145, 719.

Though the fundamental reason for the decline in rheumatic fever remains obscure, there seems no doubt of the importance of reducing the number and spread of hæmolytic streptococcal infections by improving social conditions and providing prophylaxis in suitable circumstances.[11]

Annotations

NEW YEAR HONOURS

The long list of honours announced last Tuesday contains relatively few medical names. Dr Janet Vaughan was eminent in hæmatology before she became principal of Somerville in 1945, and she has done fine work for the Nuffield Trust as well as for Oxford hospitals: *her new title must often have been used prematurely by her acquaintance because it is so clearly fitting.* Sir Arthur Porritt is created K.C.V.O. for his services to the Sovereign, and General Drummond, director-general of Army Medical Services, becomes K.B.E. The knighthood conferred on Prof. G. L. Brown, of University College, London, coincides with his election as a vice-president of the Royal Society: he has been a member of the Medical Research Council since 1951 and is chairman of its Royal Naval Personnel Research Committee. Finally, we note with pleasure the knighthood for Mr Charles Read, director of the Institute of Obstetrics and Gynæcology, whose helpful work as *president of the Royal College of Obstetricians and* Gynæcologists has been appreciated by colleagues both inside and outside his specialty. These names and others which are similarly respected will be found on p. 40.

POLIOMYELITIS VIRUSES BY MOUTH

Research on immunisation with live attenuated poliomyelitis viruses continues, and a *new report*[1] describes how infants of under 6 months were fed with live virus. It was known from earlier work[2] that immune serum-globulin given to children intramuscularly at the same time as live poliomyelitis virus was given by mouth did not prevent intestinal carriage of the virus or the development of an immune response. Obviously, therefore, infection with attenuated poliomyelitis viruses should be carried out in the presence of a serum-antibody "umbrella" which would probably reduce the chances of producing paralytic poliomyelitis without decreasing the immunising effect of the virus. Koprowski et al.[1] have infected a number of infants, most of whom had maternal antibody in their serum—that is, a natural umbrella. With the consent of their parents the infants were fed between 1000 and 100,000 infective doses of attenuated poliomyelitis viruses of types 1 and 2 in their bottles, the virus-formula mixture being given just before a regular feed. After they had had the viruses the infants were isolated in hospital and everything which was removed from the contaminated areas was disinfected.

Alimentary infection followed the virus feed, and virus was excreted in the stools for from 53 to 108 days. Antibody responses were satisfactory in ten infants aged 1–4 months, but of six infants less than a month old only three showed a satisfactory rise in antibody. The remaining three, who had high titres of antibody at birth, showed either a drop in antibody or stationary titres, and *further investigation of these infants will be needed to see* whether the present antibody titres persist. So far, antibody titres have remained high in five infants tested up to 7 months after feeding.

While it is useful to have this knowledge, its practical application will have to wait until the problem of virus excretion is solved. It might be possible to train children to such rigid habits of hygiene that they would not spread poliomyelitis viruses with which they were infected subclinically But the difficulties of controlling, outside hospital infants who are excreting virus for 3 or 4 months seem insuperable at the moment, and it may be wisest to concentrate on older children

FRIEDLANDER'S PNEUMONIA

PNEUMONIA caused by Friedländer's bacillus usually presents as an acute illness, but it often passes into a chronic phase characterised by suppuration and cavity formation Sometimes the disease is chronic from the start, and, as the upper lobe is often involved and penicillin is ineffective, tuberculosis or neoplasm may be suspected It is important to give appropriate treatment before the lung has been extensively destroyed, and it is widely believed that a characteristic, gelatinous, reddish-brown sputum is an early pointer to the diagnosis It is disconcerting to learn, therefore, that this type of sputum was seen in only 2 out of 17 cases of Friedländer's pneumonia recently reported by Erasmus[1], and these were the only 2 in which the diagnosis was made on clinical grounds In 14 of these cases Erasmus regarded the Friedländer bacillus as the primary invader of the lung, since it was isolated from the sputum in pure culture or as the predominant organism on at least two successive days, and it was thought to be a secondary invader in the other 3 cases in which it was recovered from the sputum in association with other organisms on at least two successive days Erasmus emphasises that a Friedländer infection is especially likely to be overlooked when it is superimposed on existing pulmonary disease

Amberson[2] suggested that Friedländer's pneumonia is caused by the aspiration of infected secretions from the upper respiratory passages into the lung, and Erasmus found evidence that both the primary and the secondary invaders reached the lungs in this way Compared with non-suppurative pneumonia, the disease showed a predilection for the posterior part of the upper lobe and for the apex of the lower lobe—sites favoured by non-specific suppurative aspiration pneumonia[3] In most cases there was either gross dental sepsis, with which the Friedländer bacillus is commonly associated,[4] or other upper respiratory tract infection Moreover, the Friedländer bacillus is present in the mouth or upper respiratory tract in 1–5% of normal individuals[5] In some older persons there was multifocal disease in the lower lobes, and this was attributed to the failure of a feeble cough to get rid of infected secretions

There is evidence that streptomycin,[6–13] chloramphenicol[14–16] and sulphadiazine[13 17–19] are effective in this condition In vitro sensitivity tests in Erasmus's series showed that the organisms were sensitive in all 15 cases tested to streptomycin, in all but 1 to chloramphenicol, and in two thirds to sulphadiazine All the organisms were resistant to penicillin and erythromycin, and more than half were resistant to chlortetracycline (aureomycin) and oxytetracycline (terramycin) Most of the patients were successfully treated with a combination of streptomycin and sulphadiazine, but Erasmus recommends that chloramphenicol should be substituted for these drugs after a few days since resistance to streptomycin may rapidly develop[11] In his experience with these patients, the disease, though serious, did not sustain its formidable reputation none of the patients died and in only 2 was the lung damage severe enough to require surgical resection The fact that effective treatment is now available makes early diagnosis all the more important, and Erasmus's experience suggests that this is more likely to be achieved by the bacteriologist than by the clinician

CONGENITAL ANGIOMA OF THE PAROTID GLAND

THE technique of operations on the parotid gland has improved in recent years Wide exposure through an incision that is cosmetically acceptable, and preliminary identification of the facial nerve, have enabled adequate excisions to be confidently though not lightly undertaken The conditions for which these methods can be applied include the parotid angiomas, which, though uncommon are by no means so rare as to be merely a medical curiosity, and Campbell[20] has lately reported 3 such cases treated by subtotal parotidectomy He states that angioma is the most likely cause of chronic unilateral parotid swelling in the first year of life (in a series of 21 parotid tumours in children Howard et al[21] found angiomas)

The angioma is usually noticed in the first weeks or months of life as a pre auricular swelling of the consistence of rubber A clue to the diagnosis may be given by a bluish colour of the skin or by an overlying cutaneous angioma, but no case has yet been recorded in which a parotid angioma was associated with the more serious congenital vascular abnormalities, such as intracranial cirsoid aneurysm The lesion has no capsule and may spread beyond the confines of the gland It grows rapidly during the first months of life but there is no evidence of true malignant change The gross appearance, Campbell remarks, "resembled nothing quite so much as an enlarged, coarsely lobated and cyanosed parotid gland"—a point of some importance in exploration of the lesion

Excision is usually advised In the 46 recorded cases treated by surgery there were 2 deaths Radiotherapy has also been used with some success, but it may be a dangerous weapon in the treatment of a benign condition in this situation in a growing infant Glaser et al[22] describe a uniformly disastrous course if the condition is not treated, leading to death in weeks or months due to invasion and compression of the vital organs of the neck But Campbell makes the pertinent comment that only two references to such death, with post mortem evidence, appeared in the literature he reviewed[23] There seems to be some doubt about the true natural history of the untreated lesion Wawro et al[24] noted greater mitotic activity in the younger children and a tendency to quiescence in the older patients A parallel might be drawn with the behaviour of cutaneous angiomas, and it may be that parotid angiomas would later regress as most of the cutaneous ones do[25 26] There certainly seems to be a case for deferring operation for lesions which are not enlarging rapidly when first seen, but it would be helpful to have more facts Surgery has been successful and there have been very few recorded recurrences, but

the 46 cases that have been described included 11 in which facial palsy resulted. Campbell emphasises that though they are growing, these tumours are pathologically benign and that there is no justification for deliberate sacrifice of the facial nerve. The nerve runs an extremely superficial course in young children, but a careful technique should ensure that accidental damage is rare. Further knowledge of the natural history of the lesion, however, would make it easier to decide whether the operation is always justified or whether there may be a group in which it is wisest to delay. The impression is that this is one of those subjects in which much more experience and knowledge must exist than has been recorded.

HEREDITARY HÆMORRHAGIC TELANGIECTASIA

The odd condition called hereditary hæmorrhagic telangiectasia, which can cause serious bleeding from mucous membranes especially from the nose, has been known for a long time. Gawen Sutton[1] in 1864 described some curious cases of recurrent epistaxis and Babington,[2] in 1865 contributed a letter to our columns briefly listing members of 5 generations in a single family who had suffered from epistaxis; but neither of these physicians had any clue to the cause of the epistaxis in their patients. Just 80 years ago Legg[3] gave a paper to the Royal Medico-Chirurgical Society of London on "a case of hæmophilia complicated by multiple nævi": we should not now use the name hæmophilia, but there is no doubt about the nævi. This seems to be the first case of hæmorrhagic telangiectasia to be properly described, though the credit is usually given to Rendu[4] in 1896 and Osler[5] in 1901, who really gave an adequate description of the disease, noted its hereditary character and correctly ascribed the hæmorrhage to disease of the blood-vessels and not to any abnormality in blood-clotting.

Eponyms are now out of favour, and hereditary hæmorrhagic telangiectasia is the name used in all the textbooks. There are, as Stefanini and Dameshek[6] point out, two basic vascular abnormalities: in the first there are localised areas where the walls of the capillaries are extremely thin, being reduced to the endothelial layer only; in the second, there are visible dilatations of arterioles and capillaries which can lead to the formation of arteriovenous aneurysms especially in the lung. The telangiectases are normally much brighter in colour, with bigger visible vessels, than the spider nævi associated with liver disease. Their commonest site is in the nose, but careful inspection of affected patients nearly always reveals them on the lips and tongue, under the nails, and elsewhere in the skin, especially of the face and ears. The commonest form of bleeding is epistaxis, but hæmoptysis, melæna, and hæmaturia are quite frequent. Landau et al.[7] described a family in which conjunctival and retinal lesions were prominent. The hereditary nature of the abnormality is well established as a simple dominant affecting both sexes. The most striking example is that given in Wintrobe's textbook[8]: a Mormon with hæmorrhagic telangiectasia had 22 children by his 4 wives and 10 of these children were affected; in their turn these affected members of the family passed on the disease for another three or four generations and no less than 82 affected descendants of the original progenitor were known in this family when the list was put together. It is clear from this and other examples that unaffected individuals do not pass on the disease. There is also some evidence suggesting that the type of lesion is also inherited; thus, arteriovenous aneurysms are common in some affected families and never occur in others. The diagnosis of the disease is not difficult if its existence is borne in mind and if the characteristic lesions on the lips, tongue, or face or under the nails are sought in every case of recurrent epistaxis, melæna, or other bleeding for which there is no obvious cause.

The disease can be quite mild or it can be a serious burden to the patient because of the gradually increasing anæmia caused by repeated bleeding over many years. The anæmia is of the iron-deficiency type, and if the condition has been neglected it often fails to respond to oral iron and needs parenteral iron for its effective treatment. Sometimes blood-transfusion is needed to restore the hæmoglobin content of the blood as soon as possible to a safe level. The seriously affected patient may lead a miserable existence, always at the mercy of a recurrent hæmorrhage that his family doctor may be unable to control; and, if the bleeding is from an inaccessible site like the alimentary tract, admission to hospital and blood-transfusion are inevitable. The nasal, labial, and buccal telangiectases can be directly attacked. Several methods of applying pressure have been devised, and direct application of a thrombin spray will often stop the bleeding. Various escharotics, including X rays, radium, and electrocoagulation, have been tried, but they nearly always fail because new lesions tend to appear near the site of their application. Cochrane and Leslie,[9] however, were able to check bleeding in a patient with angiomas of the scalp and face by a small dose of contact X rays.

A quite different approach has been by way of treatment with œstrogens. This method arose from the observation that in affected women bleeding seemed to be worse at the end of the menstrual cycle and sometimes subsided spontaneously shortly after the onset of menstruation; so the bleeding was worst at a time when secretion of œstrogens is low and urinary excretion of gonadotrophins is relatively increased. Acting on this idea, Koch et al.[10] treated 5 patients with ethinyl œstradiol, using doses of 0·25 mg. daily—about ten times the dose given to control menopausal symptoms. In males, 5 mg. daily of methyl testosterone was given to counteract feminising side effects. Koch et al. claimed considerable success, but Stefanini and Dameshek,[6] for example, found the treatment of no value. Harrison,[11] at Guy's Hospital, has lately re-examined this form of treatment applied to 4 patients (2 men and 2 women) with typical lesions. He began by giving 0·25 mg. ethinyl œstradiol daily but gradually increased the dose to 1 mg. daily in both women and 1 of the men; the men were also given 5 mg. methyl testosterone daily. In spite of these large doses the only side effect was that 1 of the women had a uterine hæmorrhage after three months, but this did not recur in spite of continued treatment. All the patients were much improved and the hæmorrhages from the telangiectases were much less common or even stopped altogether. At the time of his report Harrison had not stopped the treatment; Koch et al. found that bleeding returned three weeks after œstrogens were stopped, and Harrison therefore proposed to reduce the dose gradually to try to find a minimum level for each patient, but he had no results to report at the time.

Sections of tissue from the inferior turbinates were taken before and after treatment in 2 cases, and they showed that the normal columnar epithelium had changed to a squamous one. It may in fact be this change which protects the telangiectases from trauma

and therefore makes them less likely to bleed The oestrogen treatment of telangiectasia thus seems worth a trial in severely handicapped patients, but, as Harrison emphasises, it is unwise to give 1 mg of oestrogen a day for long periods to young persons, and he suggests that the treatment should be restricted to women who have passed the menopause and to men of comparable age

TOADSTOOLS

To garner and consume the wild fruits of the earth is a pursuit so innocent and with such happy associations that the rare death caused by poisonous fungi is the more bitter to contemplate Our European neighbours are more venturesome than we are and are said to pay the penalty more often[1] [2] It surprised us to learn that the same peril threatens the ignorant in the Union of South Africa and that our own *Amanita phalloides* may be the species responsible (Is it a native of those parts or a chance introduction given in exchange for the nerine and the gladiolus ?) Steyn et al[3] describe two disasters which ended in the death of 5 out of 9 of those who had been tempted by the prevalence of "mushrooms" in a place where the arid climate makes them a rarity The history and symptoms showed no unusual features, but the account includes a valuable resumé of the present knowledge of the toxic effects of fungi other than *A phalloides* There is a satisfying agreement between the pharmacology of the specifically poisonous species and the symptoms which they produce *A phalloides* contains amanitine with a delayed hepatotoxic action, like phosphorus *A muscaria* and *A pantherina* contain muscarine (parasympathomimetic) and myceto-atropine (parasympatholytic) symptoms and treatment will depend upon which of these antagonists is the more abundant Both species, by the way, taste horrid The genus Inocybe contains muscarine alone Besides these, there are many species described as "sometimes poisonous" and that should be warning enough, even though one of these is named *Helvella esculenta*

The traveller in France who finds strange and flabby shapes on his plate will be comforted if he sees others eating the same dish, in some instances his palate will be rewarded If on his return he wishes to persuade his wife to add variety to his diet, he will be foolish if he does not arm himself with the Ministry of Agriculture's guide to epicurean adventure[4]

THYROXINE-LIKE ACTION OF ASPIRIN

As long ago as 1919, Barbour and Devenis[5] showed that single doses of aspirin caused an increase in both oxygen consumption and carbon dioxide output in normal persons These observations were confirmed a few years ago by Cochran,[6] and now Alexander and Johnson[7] have shown that the low basal oxygen consumption (B M R) of patients with myxoedema can be restored to normal by giving aspirin in doses of about 8 g (gr 120) daily They also showed that their patients' serum cholesterol levels fell during treatment with aspirin The two measurements of B M R and serum cholesterol are normally taken as the best objective index of response to thyroid hormone treatment, and in both these respects Alexander and Johnson's patients responded as well to aspirin as they did to triiodothyronine But they did not feel any better although warmer, they were still sluggish and sleepy, skin and voice remained characteristic of the myxoedematous state, and they did not lose weight These observations recall Dodds and Robertson's demonstration[8] that dinitro *o* cresol can restore the B M R to normal without changing the clinical signs of myxoedema—although in this instance the analogy with thyroxine is less close, because dinitrophenols do not affect the serum cholesterol[9] Alexander and Johnson's work shows clearly that neither a rise in B M R nor a fall in serum cholesterol, even occurring simultaneously, can be regarded as specific effects of the thyroid hormones

Alexander and Johnson have drawn certain practical conclusions from their findings Two of their patients had angina, which was apparently unaffected by the rise in B M R brought about by aspirin, although it became worse when an approximately equal rise was induced with triiodothyronine They go on to suggest that a mixture of aspirin with very small doses of triiodothyronine or thyroxine might be rational treatment for those difficult cases of myxoedema in which angina is induced (or aggravated) by thyroid preparations But it is hard to see that such patients would be any better off after the consumption of large doses of aspirin, for Alexander and Johnson showed that it does not make them feel any better The only hypothetical benefit from this combined treatment would come from the lowering of the serum cholesterol level There is certainly some as yet undefined association between serum cholesterol levels and the occurrence of coronary atherosclerosis, but it is not known whether lowering the serum cholesterol level actually retards the development of coronary disease At the moment, this hypothesis, interesting though it is, hardly seems to justify imposing on patients the side effects of large doses of aspirin

In a further suggestion of more immediate practical importance, Alexander and Johnson point out that patients with rheumatic heart-disease are often treated with large doses of aspirin, and that in some cases the increase in metabolic rate induced by aspirin may add considerably to the burden on the heart This is clearly something that needs investigation, but in the meantime it seems desirable not to prolong aspirin medication in acute rheumatism after the rheumatic process has subsided

THE REFUGEES

Of the two score medical refugees who have so far reached these shores from Hungary, some plan to remain here and others to continue their journey All are anxious for news of when they can travel or how they may obtain employment here

Employment —The Ministry of Health has not announced any special arrangements for the employment of refugee doctors in British hospitals, but there is reason to hope that regional boards will establish temporary supernumerary posts Inquiries regarding professional opportunities here and overseas may be addressed to the British Medical Association's International Medical Visitors Bureau B M A House, Tavistock Square, London, W C 1 (tel Euston 1490)

Finance —Refugees who have left official transit camps and hostels may apply to the local office of the National Assistance Board for regular grants Those needing money for special expenses, such as clothes and necessary journeys, should write to the *Lancet* office where a small fund has been started for this purpose[10]

Accommodation — We are in touch with medical households who have offered accommodation to Hungarian colleagues and will try to find a temporary home for anyone needing it

Inquiries or requests for help should be addressed either to this office or to Brigadier H A Sandiford M C, medical director of the B M A 's International Medical Visitors Bureau

MEDICOSOCIAL WORK IN A GENERAL PRACTICE

E MAURICE BACKETT
M B, B Sc Lond, M R C P, D P H
LATELY LECTURER IN SOCIAL AND PREVENTIVE MEDICINE IN THE QUEEN'S UNIVERSITY OF BELFAST

R P MAYBIN
M D Belf
GENERAL PRACTITIONER

YVONNE DUDGEON
SOCIAL WORKER, DEPARTMENT OF SOCIAL AND PREVENTIVE MEDICINE, THE QUEEN'S UNIVERSITY OF BELFAST

MUCH of the discussion on the changing rôle of the health visitor is about the extent to which she can act as a social worker as well as a public health nurse (*Medical Officer* 1954, Hughes 1954, MacQueen 1955, An Inquiry into Health Visiting 1956) As part of this argument it is often implied that there is an unmet need for social work in our community (e g, Roberts 1953) and that meeting this need is part of good medical care (Minister of Health 1953, Roberts 1953) If the job of the health visitor is to have more to do with the social care of the families which she and the family doctor serve, as the working party suggest, it is imperative to know the nature and extent of the need, particularly the unmet need, which exists

There have been few attempts to survey unmet medical or social need, and those that have been made (e g, Horder and Horder 1954, E M Backett and J C Evans unpublished) have faced great difficulties The discovery of an untreated case of diabetes, for example, clearly represents an unmet need for medical care and can be classified and described as such, but the discovery of a family breaking under the weight of problems such as overcrowding, unemployment, and the care of the elderly quick falls into no such clear cut category It is even doubtful whether a need for social care exists in such cases unless help is sought by the particular family, and there is great individual variation in the attitudes of practitioners to these problems Some view the social disorganisation of the home as a problem needing solution whether obviously related to the medical needs of patients or not and regardless of whether help is sought Others, mindful of the importance of the initiative coming from the patient, confine their activities to more strictly medical matters and feel that the most that is needed is to put the family in touch with any social agencies who can help

Purpose

We describe here an investigation of the need for social work in a general practice in 1954–55 The inquiry was part of a series of small scale studies of a general practice which ranged from an examination of the most convenient form of clinical record (Backett and Maybin 1956) to a study of family patterns of illness Its purpose was fourfold (1) to see how much someone trained in social work could help the family doctor, (2) to describe the extent of her work, and the types of problems encountered, (3) to measure the extent of unmet need for social care in the practice, and (4) to record the other agencies involved in dealing with problems among the families in the practice Finally, an important aim was to bring about closer cooperation between workers from the local health authority and the general practitioner by regular meetings for discussion

Because of the relative prosperity of the area, the almost complete absence of slum property, and the low level (for Northern Ireland) of unemployment, it was expected that few serious social problems would be met For this reason the study might serve the general purpose of giving a " base line " or an idea of the minimum of social work to be expected in general practice

Method

One of us who is a qualified social worker employed by the department (Y D) spent three-quarters of her full time working with the practitioner in his practice Her full time could have been made available if necessary Supervision of her work and of the study was arranged through weekly case conferences in the department or at the practice, when current medical and social work was reviewed and immediate aims were decided on

Records

The following records were kept for the full year 1954–55

(1) The age, sex, family, and occupational structure of the practice

(2) All episodes of illness observed and the consultations involved

(3) Diagnoses

(4) The day to day work of the social worker, the problems she met, and the families and individuals with whom she worked

During the early part of the study the address of every registered individual was visited and details of the practice population were recorded This visit was made the occasion for an explanation of the job of the social worker in the practice, and an opportunity was thus given for the raising of problems at once or for an invitation for a return visit Social work of some kind was undertaken where a need was found at this initial visit, where a request for help was expressed then or later, or where the practitioner asked the social worker to visit the family All new entrants were visited in the same way

Social Problems

To avoid the obvious difficulties of definition, a social problem was regarded as any problem tackled by the social worker with the agreement, or at the request, of the general practitioner A working classification is shown in table I

Results

THE PRACTICE

The practice in which this study was made had an average of 1371 persons registered with the principal during the year of the study It is a rural practice situated some six miles from a large city The standard of living and of housing is high, and the average earnings are good Work is mainly agricultural, but some of the population travel daily to and from the city An average of 185 individuals aged 65 or more (13 5% of the practice) were registered, and there was an average of 302 children

TABLE I—PROBLEMS CLASSIFIED BY TYPE AND METHOD OF ASCERTAINMENT

Type of problem	No of times encountered during the year	Ascertained through	
		Medical care	Social worker
Associated with chronic illness	28*(*24%*)	15 (*13%*)	13 (*11%*)
Marital family or neighbour friction	19 (*16%*)	11 (*9%*)	8 (*7%*)
Old age	13 (*11%*)	8 (*7%*)	5 (*4%*)
Administrative (e g, insurance)	11 (*9%*)	6 (*5%*)	5 (*4%*)
Housing	9 (*8%*)	2 (*2%*)	7 (*6%*)
Inability to maintain personal or family standards	9 (*7%*)	5 (*4%*)	4 (*3%*)
Financial	7 (*6%*)	4 (*3%*)	3 (*3%*)
Loneliness	6 (*5%*)	2 (*2%*)	4 (*3%*)
Other (see text)	16 (*14%*)	1 (*1%*)	15 (*13%*)
Total	118 (*100%*)	54 (*46%*)	64 (*54%*)

* Including 8 where a psychiatric diagnosis had been made

TABLE II—FAMILIES CLASSIFIED BY METHOD OF ASCERTAINMENT AND NUMBER OF TIMES VISITED

Method of ascertainment	No of visits				No of families *
	1	2–4	5–8	8 +	
Medical care	1(*5%*)	9(*45%*)	2(*10%*)	8(*40%*)	20(*100%*)
Social worker	14(*37%*)	18(*47%*)	4(*11%*)	2(*5%*)	38(*100%*)

(Combining cols 5–8 and 8 +)
* Includes 2 single persons living alone

aged less than 15 (21% of the practice) on the practice records

Families in the Practice

If a family is all the related persons living at an address, as well as single persons living alone, there were 467 families represented in the practice by the end of the year This figure included 27 elderly persons (i e aged 65 or more) and 23 young or middle-aged persons living alone

Of the families of two or more persons represented on the practice records, 78% were "complete"—i e, all members of the family were registered with the practice at some time during the study For these families, therefore, the doctor could be said to be a "family doctor"

THE NEED

In the course of the initial visits of the social worker to everyone in the practice or during medical care 118 social problems were met Social work directed toward meeting the needs of families with these problems was undertaken in 58 cases

Ascertainment of Need

Of these 58 families with social problems 20 were met in the course of medical treatment and the remaining 38 by the social worker during her routine visits (table I) None of the 64 problems of the latter had been brought to the notice of the practitioner before they were found by the social worker and they represent a crude measure of the unmet need for social care in the practice which existed at the time

Table I suggests that the social worker did not discover different types of problems from the practitioner except in the housing and "other" (unclassifiable) group Of the latter, 6 were based upon a fear of disease and others were problems associated with vocational guidance, illegitimacy, infertility, &c *In each there were obvious* reasons why the practitioner had not been consulted Some interest attaches to the problems where the social worker succeeded in encouraging consultation with the doctor There were 16 families where this was the case, and medical action taken after the consultation included an amputation of cervix, references to hospital fertility and birth control clinics the exclusion of carcinoma in several cases, and a variety of X ray and other diagnostic tests

Social problems ascertained by the social worker required significantly less visiting than those found during medical treatment (table II)

Frequency and Seriousness of Problems

23 families had only 1 obvious problem. 20 had 2 problems, and 15 had 3 or more For 2 of the latter there were 6 or more problems at the same time

No attempt has been made to estimate the seriousness of the problems encountered, because there are no objective criteria, but the extent of the care which was actually undertaken may be related to their seriousness. Two groups of families can be defined for this purpose (1) 28 families visited once or twice, and (2) 30 families visited three or more times

The needs of the less frequently visited group were largely concerned with appeals, applications, certification, &c, or with short or sudden problems of illness The needs of the more frequently visited families were for help with such long-term problems as relationships (e g, family or neighbour friction) or with problems of adaptation to chronic illness or old age

Requests for Help

35 families asked for assistance with their social problems The remaining 23 families permitted visits without encouraging them in this way and cooperated when necessary with the social worker Therefore, in these 58 families there seemed to be some recognition of their needs In none of her routine visits was the social worker refused admission, but there is, of course, no way of estimating the extent of problems not brought to her notice or to that of the practitioner Indirect evidence from practice records suggests that some serious problems were untapped by these methods of ascertainment

Of the less frequently visited families just under half, and of the more frequently visited families over two thirds, requested help at the beginning

THE WORK

In attempting to meet the needs set by the social problems of the 58 families 227 visits were made, involving 118 hours of social work The frequency of visiting is set out in table III, which shows that, for about a quarter of the families in the group, five or more visits were necessary, and that about 60% of all the social worker's time was taken up in their care Social work involved in assisting one family which was breaking up during the study took up as much time as did the 15 families for whom only one visit was necessary

Other Agencies

Sixty meetings with agencies on behalf of the 58 families were made during the year 33 of the families were already in contact with other agencies, usually of the local health authority Already concerned in the social problems of these families were the National Assistance Board and its visitors, the *Ministry of Labour* and National Insurance, the welfare authority, and the police Most common among agencies approached by the social worker were those of the local health authority

* 1, *young families or young couples*: young families are at least one adult living with at least one child aged less than 15; young couples are aged less than 45.
2, *young or middle-aged families with elderly persons*: these are at least two generation families in which there is at least one person aged 65 or more.
3, all other types of family.

In addition there were numerous other meetings with hospital almoners, psychiatric social workers, the Northern Ireland Housing Trust, the Care and After-Care Committee, the National Council for Social Welfare, Churches, the N.S.P.C.C., the Marriage Guidance Council, &c. Of the 42 first approaches made by the social worker to agencies, 36 were in the course of the social care of the frequently visited families—i.e., among those with whom most social work was done.

Meetings with other agencies were at the rate of 0·4 per family per annum in the less frequently visited group and at the rate of 1·6 per family per annum among the more frequently visited.

THE FAMILIES

Social Characteristics

Some distinguishing characteristics of the families needing social care were tested by comparing them with the practice as a whole. The results are given in table IV, which shows that the group of families and individuals cared for by the social worker differed significantly from the practice as a whole only in that it contained fewer old people and fewer people living alone. This finding was contrary to expectation. There was an excess (insignificant by conventional standards) of middle-aged families in the social-care group and more were completely registered. Differences in health experience between the social care group and the rest of the practice will be discussed elsewhere.

Differences within the social-care group itself distinguish the more frequently visited families as of lower social class than the less frequently visited families (P = 0·02). Again, among the more frequently visited families, consultations with the doctor (but not illnesses) were in excess of those among the less frequently visited families. There was no excess of serious illness among those visited more often by the social worker. Families which were "incompletely" registered took up a disproportionate amount of the social worker's time.

Discussion

Four questions were asked in this study:

(1) How much could someone with social work training help the family doctor?

(2) What was the extent of her work and the type of problem which she met?

(3) How much unmet need for social care was there in the practice?

(4) What were the other agencies involved?

(1) The question of how far the social problems of his patients should be the concern of the family doctor cannot be answered by this or any other study. Many of the social problems met during this inquiry were part of the repercussions of illness or were thought to be so by the patient. These were obviously the concern of the practitioner. Others were not even remotely connected with medical care, but in spite of this the family doctor was consulted. In this particular practice the doctor would have wished to deal with the social problems which he met, regarding such work as an essential part of his job. The presence of a social worker with time to care for the families was therefore of assistance to him only in the sense that it left him more time for what has been called "real medicine." The fact of her special skill in social work may also mean that the social worker did the job better than the doctor would have done it, though from his standing with his patients he would have gained initially.

Though a social worker was a help to the practitioner, there is no similar evidence from the point of view of the patient. The successes of curative medicine obviously have no parallel in social care. Though it is true that many agencies were mobilised to help those thought to need assistance, and that support was given to others in obvious need, a truly successful outcome of social care is hardly to be expected in view of the intractable nature of some of the problems. For example, of the 7 problem-ridden families visited nine or more times, with whom over a third of the work was done, all had long term problems which continue today, unchanged by the attentions of doctor or social worker. For 2 of the 7 (a young family in which the mother has rheumatic heart disease with severe decompensation, and a family in which a very difficult and ill grandparent is living) the social worker may have assisted in establishing some equilibrium. For the others the problems continue to disturb the household, and family crisis follows family crisis, some apparently serious (as when a young wife abandoned her husband and children), and others, from the doctor's point of view at least, trivial.

Probably the social worker was of most value to the doctor and his practice in uncovering problems which were medical as well as social and where she was able successfully to urge consultation.

(2) The extent of the work and the type of problem considered to be within the scope of the social worker have been described above. It is impossible to estimate how well the needs arising as a result of these problems could have been met by the general practitioner acting alone, or by other members of the domiciliary team—e.g., the health visitor. Undoubtedly some help would have been given, but it would have been relatively unskilled. However, it is worth noting in this context that, of the 118 problems tackled by the social worker, 4 of every 10 (45) were concerned with established illness

or with possible illness or were of the type where medical knowledge would be an advantage In dealing with this aspect of her work it was the social worker who lacked skill It is our opinion that the special relationship of the family doctor to his patients enables others working close to him to have ready access to them For various reasons an introduction from the doctor may be the best way to ascertain the patients' social problems The health visitor, unless she can be identified by the patient more closely with the general practitioner than is our experience elsewhere, will not benefit, and however skilled she may be she will not have such easy access This contention is supported by the experience of the health visitor who is now working in close cooperation with the doctor in this practice and is at the same time studying social case work in a nearby university department

(3) A measure of unmet need for social care is provided by the number of problems ascertained only by the social worker (64 of 118) The number of times that the families with these problems were visited suggests that the problems ascertained by the social worker were either among the less serious or more easily resolved Of the 38 families whose problems were ascertained by the social worker, 8 were already in contact with other agencies The hard core of unmet need therefore, which is left, amounts to 51 problems in 30 families (6 4% of all those registered)

(4) *Other agencies were already concerned in the care* of 33 of the 58 families, but their activities were uncoordinated and their individual duties limited In only a few cases was the work of the agency known to the practitioner and then through informal rather than formal channels The large number of contacts made with agencies by the social worker suggests that one of her main contributions to the work of the practice was in mobilising and coordinating this kind of help

Summary

Discussion of the changing rôle of the health visitor turns on the amount of social work which she should undertake To investigate the need for this type of work a social worker was attached for a year to a small practice in a moderately prosperous rural area Social work resulted from ascertainment of problems by the practitioner in the course of his medical work and by the social worker at routine visits to every family in the practice

Social work was undertaken among 12% of the families, the doctor ascertaining just under, and the social worker just over, half of their 118 problems Social work with these families involved 227 visits, 118 hours of interviews, and 60 meetings with other agencies

The families with whom social work was undertaken differed significantly from the rest of the practice only in that there were fewer old people among them and fewer persons living alone Unmet need for social work is represented by the 51 social problems of 30 families which would not otherwise have been ascertained Important contributions of the social worker were in encouraging consultation with the practitioner and coordinating the work of social agencies

The suggestion that social work in general practice be undertaken by a specially trained health visitor is discussed

It is estimated that one full-time and suitably trained worker might do the social work of a general practice of this type with a registered population of 4000

This study would not have been possible without a generous grant from the Northern Ireland Hospitals Authority

We are grateful to Dr J B McKinney, medical officer of health for County Down, Miss E W Gracey, the county nursing officer, Dr S Hayes and Miss E J Johnston of his staff, Miss E M Doran, of the Care and Aftercare Committee, and the families and individuals in the practice who helped us with this study We are also grateful to Mr J D Merrott, Mr J S Crockett, Miss P Stewart, and Miss P Bone for their help in preparing the tables and manuscript and to other colleagues in the department Our thanks are due particularly to Prof A C Stevenson and Dr E A Cheeseman for their advice and help

NEW YEAR HONOURS

The list of honours published on Jan 1 contains the names of the following members of the medical profession

K C V O

Sir Arthur Espie Porritt, K C M G , C B E , M CH Oxfd, F R C S
Sergeant Surgeon to H M the Queen , surgeon to St Mary's Hospital, London

K B E (Military)

Lieut General William Alexander Duncan Drummond, C B , C B E , F R C S
Director general, Army Medical Services

D B E

Janet Maria Vaughan, O B E , D M Oxfd, F R C P
Principal, Somerville College, Oxford

Knights Bachelor

George Lindor Brown, C B E , M B Manc , F R S
Jodrell professor of physiology, University College, London

Charles David Read, M B N Z F R C S , F R C O G
President, Royal College of Obstetricians and Gynæcologists

C B (Military)

Major General Alfred Edward Campbell M D Belf , Q H P
Air Vice Marshal John Conrad Neely, C B E D M Oxfd Q H S

C B (Civil)

Sir Weldon Dalrymple Champneys, Bt D M Oxfd, F R C P
Lately deputy chief medical officer, Ministry of Health

C M G

John George Hunter M B Sydney
General secretary of the Federal Council of the British Medical Association in the Commonwealth of Australia

C B E (Military)

Surgeon Captain David Herbert Kernohan, M B Belf R N
Surgeon Rear Admiral Lionel Lockwood M V O D S C M B Melb

C B E (Civil)

Harold Maurice Cohen, M D L'pool
Principal school medical officer, Birmingham

Humphrey Francis Humphreys O B E M C T D M B M D S Birm F D S R C S D L
Vice chancellor and professor of dental surgery University of Birmingham

John McQueen Johnston, M D Glasg F R C S E M R C P E
A principal medical officer Department of Health for Scotland

RONALD EDEY LANE, M D Lond , F R C P
Member, Industrial Health Advisory Committee Nuffield professor of occupational health University of Manchester

JOSEPH ANTOINE RENÉ LAVOIPIERRE, M D Paris, L R C P E
Director of medical services, Mauritius

JOHN FREEMAN LOUTIT, D M Oxfd F R C P
Director, radiobiological research unit, Harwell

GEORGE WILLIAM JOHN MACKAY M B Edin
Medical superintendent, Rampton Hospital

WILLIAM NORMAN PICKLES, M D Lond , M R C P
Lately president, College of General Practitioners

RALPH WHISHAW, M B Sydney F R C P F R A C P
Honorary physician, Royal Hobart Hospital, Tasmania

CHARLES FRANCIS WHITE O B E M D Manc
Lately medical officer of health City of London , recently president Society of Medical Officers of Health

O B E (Military)

Lieut Colonel JOHN GEOFFREY WAUGH, L R C S E R A M C

O B E (Civil)

LESLIE WILSON BANKS, M B Edin
Senior medical officer (clinical), Western Region, Nigeria

WILLIAM JOSEPH BRANDAY M R C S
Superintending medical officer (specialist), Trinidad

ARTHUR BARRETT CARDEW, M C M B Lond F R C S E
Commissioner, St John Ambulance Brigade, Gloucestershire

WILLIAM MICHAEL COURT BROWN, M B St And F F R
Director group for research on general effects of radiation, Medical Research Council

WILLIAM RICHARD SHABOE DOLL M D Lond. M R C P
Senior member, statistical research unit, Medical Research Council

HENRY JOHN CHADWICK HANRAHAN M B Melb
Medical practitioner, Albany Western Australia

RICHARD WILLIAM DAVID MAXWELL, M B
Lately deputy director of medical services Fiji

SYDENHAM FREDERICK MOORE M B Oxfd
British subject lately resident in Egypt

HAYDN JONES MORRIS, M R C S
For public services in the Federation of Rhodesia and Nyasaland

ERIC PARRY, M B E , M B Lpool F R C S
Chief medical officer, Kuwait government

WALTER LAING MACDONALD PERRY, M D St And
Director, Department of Biological Standards National Institute for Medical Research

JOHN CHARLES ROBB, M D M CH Belf
Consulting surgeon, Downe Hospital Downpatrick, co Down

GEORGE SIMPSON, M B Melb , M R C P , F R C O G
For services to the Flying Doctor Service of Australia

WILLIAM ARTHUR LEIGH TUCKER F R F P S , F R C S E
Surgeon specialist, Aden

M B E (Military)

Major JOHN VAUGHAN BRADLEY, T D , M B , F R C S E

M B E (Civil)

OLIVE GUMPRICH M B
For social welfare services in Southern Rhodesia

SYDNEY DOUGLAS GUN MUNRO M B
Resident surgeon, Colonial Hospital, St Vincent Windward Islands

ALEXANDER DAVID BAIN MACKIE M B Birm
Chairman Birmingham ' Stirling ' Sea Cadet Corps unit

GEORGE DAVIS McLEAN, M R C S
Medical officer, St Kitts Leeward Islands

ROBERT CUTHBERT OGG, M B Edin
Formerly a medical officer in Basutoland

FRANK BLACKLOCK THOMSON M B Edin
Deputy chairman, Dundee National Service medical board

Reconstruction

IMPROVEMENT OF THE N H S

IN his Malcolm Morris lecture on Clinical and Community Medicine, given in London on Dec 6 under the auspices of the Chadwick Trust, Dr J N MORRIS said that maintenance of the quality of medical services is a responsibility of the profession to itself and to the community It is true that much medical care of the highest quality is going on all the time (and should not be taken for granted) , but it is also true that there are more and more procedures, easily performed, whose accuracy needs to be regularly checked By way of illustration he cited the following figures

Prevalence of Otitis Media per 1000

1951	School health inspections	7 6
1954–55	National Service examinations (rejections only)	32 0

Should not more cases have been found at the school examinations than at 18 years of age ? Such follow-up provides a means of assessing the work of the school health service—of laying on a routine check of the routine examinations—and it is applicable on local or national scale, sample or total basis

Every system in Dr Morris's view, needs itself to be regularly scrutinised, and routine systems need built-in controls of quality This is widely accepted in industry, in biochemistry laboratories, and in bacteriology and there is great scope for its application in clinical medicine and the health services At present remarkably little attempt is being made to ascertain how our £500 million health service is working what are the needs to be met and how well they are being met Take the prescription of drugs, for instance In 1954 the average prescription rate in the county boroughs was about 6 The following are the towns with over 7 and under 5

	Over 7 per head		*Under 5 per head*
Wigan	8 9	Tynemouth	4 2
Warrington	7 9	Southampton	4 5
Wakefield	7 6	Coventry	4 7
Liverpool	7 4	Middlesbrough	4 8
Manchester	7 3	Great Yarmouth	4 8
Oldham	7 2	Grimsby	4 8
Burnley	7 1	Ipswich	4 9
Salford	7 1	Gateshead	4 9
		Worcester	4 9

What do these figures mean ? Would not a cooperative inquiry by the local medical committees of these towns and, in particular a comparison of North-East with North-West be of far more than local value—not only in finding answers but in showing how to tackle such questions

Dr Morris mentioned a small investigation by the Central Middlesex Hospital where certain X-ray facilities are now freely available to practitioners The 160 doctors who used the service a little produced half the " positives," while the 40 who used it a lot produced the other half If the 160 had used the service as freely as the 40 the number of " positives " might well have been more than doubled All the big users had qualified since 1925 Dr Morris gave this as an example of analysis that can be made very easily and which yields results immediately applicable in an educational campaign among doctors Because the object of such investigations, of course, is to *improve* the quality of care

It may well be he added, that one of the main results of the Guillebaud Committee's work will be a considerable increase in " operational research " of different kinds on health services But it is to be hoped that their proposal that the research unit should be centred in the Ministry of Health will be examined very carefully What is needed is opportunities for a lively group of independent-minded research-workers to devote themselves to this kind of inquiry , and a Ministry might not be the ideal milieu There are several other possibilities

Turning to the structure and functions of health services, Dr Morris pointed out that this is a revolutionary era in medicine as in so much else, and the movement towards merging of clinical and community medicine—of curative and preventive medicine—will render the tripartite structure of the National Health Service out of date. As the chronic, metabolic, and "degenerative" diseases occupy more and more of the work of medicine, growing attention will have to be paid to what is called in America "secondary" prevention—the discovery of cases early so that their progress can be limited. In this context the distinction between "preventive" and "curative" (e.g., public health and general practitioner) serves no very useful purpose, especially if, as is conceivable, most of the preventive work in the future is done by the clinical services. In America the emphasis is on ad hoc screening to detect disease early: in our own country the realistic hope is that such programmes can be incorporated into the daily work of the health service. As for "primary" prevention, we are moving into a new era in preventive medicine where the individual will have to take an increasing responsibility for his own health in the light of the discoveries which are being made about smoking, diet, exercise, and so on. The kind of health education that is already needed involves the family doctor as much as, or more than, the medical officer of health. Whatever form of organisation is appropriate, it could scarcely be less geared to such tasks than the present division of local health authority, executive council, and medical committee. Meanwhile, as the rising figures of cigarette consumption in both sexes show, *Homo insapiens* is not being helped much by any of the services.

The successful treatment of the aged, with its emphasis on the maintenance of independence and the prevention of disability, involves the freest possible traffic between all the varied services now provided by the three parts of the health service and by the welfare authorities. The same principle now arises in the treatment of the mentally ill: hospitals, general practitioners, and social services; care, aftercare, and preventive care—all have to be used in combinations varying with the needs of the individual patient. The present structure of the N.H.S. is at best irrelevant to these problems. More generally this applies to the movement towards home and family care which is one of the healthiest in modern medicine.

"Today's answer to many of these problems is the intelligent use of the committee system and good human relations all round; but it may be questioned whether this is enough. And there are other problems, such as those of the provision of a comprehensive industrial health service, which raise issues that go further than any I have mentioned. For, in effect, we have a quadripartite and not merely a tripartite health service today."

In 1945–46, Dr. Morris thought, nothing very different from the National Health Service Act was possible. But after ten years of the Act, and now that the Guillebaud Committee has cleared away the confusions about finance, the question of a fundamental reconsideration of our health services arises. It may well be practicable to rearrange the structure so that it can be a positive stimulus and the active agent of further progress.

Public Health

THE HEALTH OF THE SCHOOL-CHILD

NOWADAYS children have a much better chance of surviving their schooldays than they had even a few years ago. In 1955, 2753 children aged 5–14 died, compared with 9017 in 1938. These figures are given in the report for the years 1954 and 1955 of the chief medical officer of the *Ministry of Education*.[1]

The vast majority of absences from school are due to infections, but the infectious diseases cause many fewer deaths than formerly; since 1938 the annual number of deaths due to tuberculosis has fallen from 973 to 51, and those due to diphtheria from 1733 to 5. But diphtheria occasionally breaks out, particularly where the proportion of children immunised is low; only by continuing to immunise most children can we hope to prevent a resurgence of the disease. Because of the havoc among children which can follow pulmonary tuberculosis in their teacher, initial and regular radiography of all teachers is desirable. A Medical Research Council trial showed that, after vaccination with B.C.G., the risk of tuberculosis developing in adolescence was roughly halved.

In 1955 the number of deaths among school children from infections of all kinds was almost equalled by the number of deaths from leukæmia and cancer, but was far exceeded by the number killed in accidents—401 on the roads and 185 elsewhere. As almost every accident is preventable these deaths are the most regrettable of all. Some maladies which cause suffering, loss of school time, and a few deaths are almost equally preventable. These include dysentery and food-poisoning. Much can be done at school, by repeated instruction in hygiene, to prevent outbreaks.

In the early days of the National Health Service there was a shortage of applicants for the posts of school medical officers, but recently there have been more good candidates. The number of dentists in the service is higher than ever before, but as many again are still needed.

The number of registered blind children, which had previously been falling, has been rising since 1918. Most of the increase is attributed to retrolental fibroplasia, and the numbers are expected to fall in future now that the cause is known and few infants are affected. The large numbers with defective vision (correctable by spectacles) and hearing emphasise the necessity for examining the children as soon as possible after they enter school. Headaches and suffused conjunctivæ due to watching television are becoming commoner, but are unlikely to be troublesome if the child sits on a level with the screen and over six feet away, and goes to bed at a reasonable hour.

Many new schools have been built since the late war, and some, notably those in Hertfordshire, have attracted much favourable attention from students of architecture. Inquiry in selected areas revealed no definite improvement in the health of children attending the new school, though some doctors, teachers, and administrators were convinced that there had been an improvement in the health, vitality, and bearing of the children.

The general condition of our school children seems to be improving. Their height and weight are increasing; the number reported as being in poor condition fell from 2·6 in 1952 to 1·5% in 1955, and most are well clad, well shod, and free from body vermin; the number with infestations of the scalp is still very large, but decreasing.

Few education authorities have taken advantage of a regulation of 1953 which allows them to experiment with fewer than three periodic medical inspections. "The need now is for more individual attention to be given to children who are not thriving or who are not making satisfactory progress at school, whether on account of physical, mental or emotional reasons." Mass examination of school entrants, mass radiography of teachers, mass inoculation—all have contributed much to the welfare of our children, but it is heartening to find in the report this emphasis on the special needs of the individual.

* * *

Expectation of Life

On the basis of the mortality experience of 1955 in England and Wales[1] the expectation of life of a boy at birth is 67.52 years and of a girl 72.99 years. The comparable figures based on the mortality experience of the years 1953–55 are 67.46 and 72.86.

Towards Clean Air

Under an order[1] by the Minister of Housing and Local Government certain provisions of the Clean Air Act, 1956,[2] came into operation on Dec. 31. These include the provisions enabling local authorities to create smoke-control areas in which the emission of smoke from buildings will be an offence. Other provisions of the Act which came into force on Dec. 31 deal with the following:

New furnaces.—All new furnaces, other than small domestic boilers, must be, so far as practicable, smokeless. Notice of intention to install such a furnace must be given to the local authority.

Smoke measurement.—The Minister is empowered to make regulations requiring furnaces to be fitted with smoke density meters.

Height of chimneys.—The height of new chimneys, other than those of houses, shops, and offices has to be approved by the local authority.

Spoilbanks.—Owners of colliery spoilbanks must employ all practicable means for preventing combustion of refuse, and for preventing or minimising the emission of smoke and fumes from the refuse.

By-laws.—Local authorities may make building by-laws requiring the provision in new buildings of such arrangements for heating and cooking as are calculated to prevent, so far as practicable, the emission of smoke.

A similar Order has been made by the Secretary of State for Scotland. The remaining provisions of the Clean Air Act, which deal with the prohibition of dark smoke and the reduction of grit and dust from industry, will be brought into operation later.

Common Lodging-houses

Just before his death in 1955 Dr. Stuart Laidlaw was awarded the PH.D. for a thesis now published[3] in which he tells how he became interested in the human stories and the hitherto unexplored social histories of the misfits peopling the Glasgow common lodging-houses. At one time these places were hotbeds of infection, but Laidlaw believed that nowadays the inmates are no more likely than any other section of the community to spread infectious disease, except perhaps pulmonary tuberculosis. There were over 100 known cases of positive sputa.

Glasgow offers some 7000 hired beds of various rougher types—4893 in common lodging-houses, 1716 in working-mens hotels, and about 400 in seamen's boarding-houses and lorry-drivers' hostels. Laidlaw visited most of them to compare accommodation standards and the clients, with particular emphasis on the personal histories of some 800 users of common lodging-houses. He found that most of these men and women were unskilled or retired people depending on help from the National Assistance Board with or without additional pensions. Some 10% were ill.

Most common lodging-houses were founded for the shifting short-stay clients of the past century, but now use has changed to long stay: 44% of the men and 29% of the women had lived there for more than ten years; only 5% were casuals and vagrants. About a quarter of them liked the free-and-easy life of a common lodging-house, another quarter put up with it for economic reasons, and the rest stayed on because of social difficulties. The outside world had found no answer for their problems. The last words Laidlaw left for us are these:

No nation which aspires to greatness must despise even the lowliest of its citizens. Its aim must be to raise them on stepping stones of their dead bodies to higher things.

For the Young

Four cheery youngsters skip across the bright cover of the *Junior Health and Hygiene Manual* issued by the British Red Cross Society;[1] its shape and layout suggest that Health and Hygiene are among the exciting topics in a growing world. Not only are the society to be congratulated on breaking away from the tradition of stuffiness in manuals and bursting into contemporary idiom, but the product itself is good beneath the wrappings. It is directed towards Youth with a capital Y with ambition and vanity and drive: show the young what worlds there are to conquer and they will do the rest. Covering all the practical points of personal hygiene and running a home, its emphasis is on competition and the pride of achievement. Community hygiene and dietetics are treated with the pictorial and slogan techniques now so familiar on our daily travels, and these subtle methods of painless instruction are cleverly reinforced towards the end of the booklet with illustrated sections on hobbies and camping gadgets.

Methods of Chemical Analysis as applied to Sewage and Sewage Effluents, which was first published in 1929, has been issued in a new edition (H.M. Stationery Office. 1956. Pp. 96. 10s.)

A summary of the powers and duties of the Corporation of London as port health authority has been published by the corporation and is obtainable from the information officer, Guildhall, E.C.2 (Pp. 16. 1s. 6d.)

Medicine and the Law

Death after Insulin Treatment

THE Manchester city coroner recorded a verdict of death by misadventure at the inquest, on Dec. 14, on a woman who died in hospital following an injection of insulin given by her own doctor at home for the treatment of mental disorder. The coroner said he was satisfied that the injection was not of the right kind of insulin and that it ought not to have been administered by a general practitioner. He believed, however, that the doctor had acted honestly and with the best possible intentions in the special circumstances with which he was faced.

The woman, aged 45, died on Dec. 8 in Crumpsall Hospital from bronchopneumonia secondary to hypoglycæmic coma following the injection.

Her husband said that on Nov. 26 the doctor gave his wife an injection. She had been racing out of the house and it was becoming very difficult to keep her under control. His wife went to sleep. She was still asleep the next day. The doctor was called and, after examining her, recommended that she be allowed to come round of her own accord. In the late afternoon her husband noticed a trickle of blood from her mouth and she was making a noise in her sleep. He called in the doctor again, and his wife was removed to hospital where she died twelve days afterwards without regaining consciousness.

In evidence the doctor said that he had tried to get the patient admitted to a mental home, but an official had informed him that he was unable to help because there were much worse cases awaiting admission. Her husband was being driven nearly out of his mind by her behaviour, and their two daughters had begged for something to be done. "I knew what should be done and I knew where it ought to be done, but these places seemed to be beyond our reach. . . . I was there in the house and I had to do something. I knew it was a risk, but I also knew that if nothing were done it might end in tragedy for other members of the family."

The coroner said that the doctor had found the patient's husband "on his beam ends" and unable to stand the strain any longer. That was why he felt he simply had to do something about it. He had tried in vain to get the patient into a mental hospital and was acting in the way he thought to be right in those conditions.

In England Now

A Running Commentary by Peripatetic Correspondents

I MYSELF stopped believing in Father Xmas some years ago, and have made no effort to perpetuate this delusion in my young But they actually saw him once, and the suggestion that it wasn't him but Uncle Donald fell on deaf ears after all Uncle Donald hasn't got a long white beard Then there are those presents inscribed (as Bill, at 5, can now just decipher) "Love from Father Xmas," and the unflinching belief of his colleagues at school, not to mention active indoctrination by the teaching staff, doubtless because they think we like it that way "Do you believe in Father Xmas?" I asked on Xmas Eve while pinning pillow-cases to their beds "Yes," they both affirmed promptly "Do you?" added Bill "No," I replied emphatically, but they were quite unconcerned "He's a nice man," said Bill Jo (3) was less sure "Don't let him come here, make him give all our presents to *Mummy at the end of the garden*" This was promised, and apart from a couple of screaming attacks the night passed peacefully We're all right now for another year

Long ago I remember an occasion (I was less psychodynamically orientated then) when I pretended to be Father Xmas before an audience below age 8, most of them well known to me So successful was my dissimulation that, as I changed upstairs, they ran to the window and *swore* that they all saw me climb into a sleigh and ride away On my return, the improbable excuse of having done the washing-up was accepted fully, and I was commiserated with at length for having missed this remarkable visitation Though the delusion is common enough, this is the only Father Xmas hallucination I have definitely met, its unanimity is noteworthy and the high I Q s of two of the 8-year-olds Yes, quite remarkable In fact I don't know silly damme, I wonder I wonder if they actually did see a sleigh out there

* * *

The ward Christmas party for patients and their visitors was held on Saturday afternoon

A quick round in the morning showed that all the beds were full with the usual selection of bronchitics, ulcers, and heart-failures But that did not deter Sister from putting on her decorations When I returned in the afternoon the ward had been transformed A large clearing had been made in the middle, and tables laden with sandwiches, cakes, and sweets had been placed along the walls The beds, together with their patients, had been moved to one end of the ward and arranged to give each patient a good view of the proceedings

These began with an entertainment Somebody played the piano A troupe of girls from the local dancing school, appropriately clad in tartans, performed a number of Highland dances with great agility A young woman sang Scotch folk-songs, sad and sweet The clergyman son of one of the patients did some conjuring, which went down well with the children A nurses' teddy-girl band played hot tunes with a tin flute, a tambourine, and a washing-board

Sister had laid on a marvellous tea, after which cigarettes were passed around and prim uniformed nurses were able to smoke with gay abandon for once in the year

As soon as the tables were cleared, dancing started Charlestons and Rock and Roll were favourites It was interesting to note convalescent progress The young woman with the subacute bacterial endocarditis was fox-trotting with the houseman The hemiplegic with jargon aphasia, beaming with smiles, was dancing with her son The obese grannie with hiatus hernia, who had defied a face-value diagnosis of myxœdema, for once did not complain of pain and was full of giggles After trifle with real cream—donated by Sister's uncle—the evening ended with Auld Lang Syne, during which my left hand was warmly clasped by the convalescent lobar pneumonia whose illness had probably followed her partiality for spirits

As I was leaving the wards the beds had already been straightened out with mathematical precision and the bedpan round was beginning

The junketings of a small-town Scottish hospital ma not last long, but while they last they could give t Chelsea Arts Ball points for verve

LIONEL WHITBY

It is the remembering face of a warrior
Grooved by the chisel of pain
With the radiance of victory
Easing the grain

The voice is a teacher's bass
And the laugh, a student's fun
The halting step becomes a grace
In such a one

With power uncorrupt he strove
And gave humanity his love
Let grief submit and comfort find
In handing on the treasures of his mind

Letters to the Editor

THE FUTURE OF NURSING

SIR,—I hope that Dr Ritchie Russell's letter will not suffer the same fate as one which I wrote to you on April 23, 1953, when I voiced a similar alarm at the trend which I thought was already apparent The fact that what I then said elicited no response was a great disappointment to me, for it suggested that the medical profession no longer felt a sense of concern regarding the training of the nurse Yet the steps which are now being taken, or are contemplated, may result in a few years in the lowering of nursing standards in all hospitals with specialist interests A comparatively small body of women will have passed through a form of "officer class" training and will have little concept of the true needs of hospitals The specialist hospitals will then have to depend in the main upon nursing aides and orderlies whose training may often be indifferent

In my last letter I advanced the view, which I still hold, that nursing as a vocation should be allowed to develop only in line with the needs of the doctor and of the public whom we both serve Yet every doctor who works in hospital is aware that much of the training which the student-nurse must now receive is more in keeping with a training for some kind of junior house-officer A perusal of the examination papers which they are required to pass, and a knowledge of some of the things they are asked at oral examinations, make such an assertion quite proper.

It has been my own recent experience to be informed by a sister tutor that the nurses would require to have lectures (*a*) on the social aspects of infectious diseases by an almoner or social worker, and (*b*) on occupational therapy in tuberculosis by an occupational therapist Since the hospital at present boasts of neither of these officers I asked if I could not give (*a*) and the chest physician (*b*) The answer was "no", and when I asked if a perhaps second-rate lecture by some unknown persons would be preferred to lectures by doctors who were regarded as highly knowledged in these subjects, I was told that the regulations ought to be followed Now, of course, it may be alleged that this sister tutor was merely being stupid, but it must be pointed out that she was a properly qualified tutor

Does it not need to be stated very bluntly that the seniors in the nursing profession who contemplate these new changes are motivated by what would be properly called snobbishness? As the numbers of nurses required increase, they see more and more applicants who do not come from the social grades which were the usual source in the past Rather than give encouragement to such entrants, they say, let us constitute some higher grade which alone can carry the unqualified title of "nurse" These repositories of much half digested learning will be better able perhaps to follow the discussions of the consultant physicians regarding differential diagnosis, interpretation of laboratory reports, or definition of treatment But the poor patient will depend for his nursing on individuals whose claim to the title "nurse" must be qualified by the words "aide" or "auxiliary" or "assistant" One might wonder whether it would not be more proper to retain the word "nurse" for the person who really nurses and find some new title for this officer grade?

Meantime, thousands of girls pass nursing by—girls who in a more sensible world would find the nursing care of sick folks a rewarding career The loose statement is often made that hospital medicine today needs more highly trained nurses The fact is that this statement requires careful interpretation—for what is wanted are many many more ordinary nurses and a few who by post-graduate training have the capacity to take charge of wards, operating-theatres, &c The latter group is a very small proportion of the former

May one suggest that the time is ripe for a new *Lancet* Commission on Nursing which would allow the medical profession to redefine in terms of the 1950's the kind of nurse this country requires?

Glasgow THOMAS ANDERSON

HEALTH FROM THE HEALTH SERVICE

SIR,—Dr Joules's statement of Dec 8 represents enlightened opinion

The real achievement in preventive medicine should not screen our failures Dr Joules argues that the public health of young people is of such an order that we should reorientate our attention to the later decades where physical illness is our most urgent problem Nevertheless, what we know of the ætiology of lung cancer, hypertension, ischæmic heart disease, and peptic ulcer suggests the causative factors are established in the habitual activities of people while they are young The suggestion that the greatest enemy of the middle aged man is his wife, who, in compensation for some other inadequacy, is over indulgent in dietary attention, reminds us that people usually marry when young, and excess body-weight may be the ultimate reward of protracted matrimonial disharmony Information on school-leavers declares that physique has never been better, but their subsequent occupational and matrimonial adjustments are uncertain and confused Can it be that the foundation of physical disorder in the 50s and 60s stems from the emotional faux-pas in the 20s? With neurotic disorder omnipresent in urban populations, we can assert that we have a youth physically equipped but emotionally unprepared for the world in which they must adjust Is this not evidence that we have not even begun to approach a general state of mental well-being? Can we be sure that physical and mental well being are separate problems?

Prof O L Zangwill[1] can say of psychology that it has so far "failed to produce anything resembling a coherent and generally accepted body of scientific theory every psychologist has perforce to create his own psychology" Prof H J Eysenck,[2] speaking of data available, states they "do not prove psychotherapy to be valueless, but rather that they fail conspicuously to show any positive consequence following its use"

But what does Dr Joules say of this terrifying situation? "Mental health, in an acquisitive and densely crowded society, can come only from a wise education by which endeavour is canalised along routes likely to bring harmony rather than internecine competition" Would it be more honest to admit that we are unable to usefully predict our future, to acknowledge our ignorance, and to recognise mental health as our great problem wherein lies the opportunity for a tremendous advance? Should we be disappointed to discover no connection between mental health and the physical illness of the 50s and 60s, at least we can ensure that our potential longevity is worth having, and is not increasingly terminated in suicide, or in the chronic mental hospital

St Paul's Cray, Kent J D PAULETT

DANGEROUS CONTAMINANTS IN STORED BLOOD

SIR,—Deaths are best prevented by eliminating common causes—not rare ones In transfusion one estimates that hepatitis kills 1 recipient in 10,000–15,000, serologic incompatibility 1 in 4000–10,000, bacterial contamination something like 1 in 350,000 Dr Aidin (Nov 17 and Dec 22) wants us to do a special test to eliminate the 1 death in 350,000, forgetting that the hurry and worry of the extra test may increase the 35–90 deaths due to serologic error, or delay the transfusion so that an occasional patient may die.

---

[2] Eysenck H J Use and Abuse of Psychology London, 1953, p 199

Dr Drummond's (Dec. 15) experience that 3·1% of entered bottles are contaminated is a sufficient refutation of Dr Aidin's belief that bottles can be entered without danger. His bacteriological test seems likely to kill more patients than it saves—at least if he continues to assume that he can enter the bottle without contaminating it. I maintain that the safest procedure is to use pilot bottles and to refrain from entering the main bottle until it is actually to be used.

GEORGE DISCOMBE.

SEVERE TOXIC REACTION TO HYDRALLAZINE

SIR,—Dr McNicol and Dr Hutchison described (Dec. 22) an unusual instance of the toxicity of hydrallazine[1] ('Apresoline'; 1-hydrazinophthalazine)—apparently *the first example of this disturbance to be reported* in the British literature. They thereby drew attention to a problem of some practical importance to the cardiologist, but of profound theoretical interest to those investigating the rheumatic diseases.

A small but significant number of patients treated with large amounts of hydrallazine for long periods have been found to develop a condition clinically resembling rheumatoid arthritis.[2,3] If the administration of this drug is continued after the appearance of these changes, a proportion of patients, again small, manifests signs which more or less closely mimic those of disseminated lupus erythematosus (D.L.E.). These changes, which include fever, anæmia, loss of weight, and splenomegaly,[4] may be accompanied by a skin rash of "butterfly" distribution. Histological examination of the involved skin may reveal changes resembling those of D.L.E.[5] In a few patients it has proved possible to demonstrate in the plasma a factor capable of inducing the formation of cells morphologically indistinguishable from the "L.E." cell of Hargraves.[6] The description of these undesirable pharmacological effects raised the hope that a means had been found by which the changes of D.L.E. might be reproduced in the laboratory animal. This suggestion has been investigated by Schroeder and his colleagues, and culminated in a description by Comens[7] of changes in the dog caused by the long-continued feeding of hydrallazine.

I have lately been able to substantiate the claim by Comens that dogs fed large doses of hydrallazine soon develop severe illness. In a paper submitted for publication elsewhere, the production by this means of severe and rapid weight loss, progressive non-deficiency anæmia, altered plasma proteins, and other changes has been described. The loss of weight was unrelated to the taste of the drug: *during the greater part of the experiment* the animals ate voraciously. Examination of suitable preparations of dog serum and human leucocytes revealed the appearance of cells resembling those described by Comens which he considered to be indistinguishable from the classic "L.E." cell; however, the histological examination of freshly fixed tissue from the majority of the organs from these dogs did not reveal changes similar to those found in D.L.E.

The question now arises: to what extent does this disorder of dogs provide an experimental replica of D.L.E.? The evidence given by Comens for considering these illnesses identical includes *the description of two specific* changes: (1) the demonstration in dog sera of a factor inducing the formation of cells similar to those produced in D.L.E., and (2) the discovery at necropsy of histological changes resembling those of D.L.E. in the human. The "L.E." cell of Hargraves,[6] to be accepted as diagnostic, must contain homogeneous basophilic material of nuclear origin.[8] The cells produced with dog sera in our experiments *do not conform to this description*. Among the histological changes regarded as being most characteristic of D.L.E. is the "wire loop" change in renal glomerular capillaries.[8] Changes of this general pattern may indeed be found in kidneys of the treated dog, they may also be found in the glomeruli of untreated animals of the same species, age, and sex.

The conclusion seems inevitable that the response of the dog to hydrallazine, while yielding an interesting parallel to the human "hydrallazine syndrome," does not provide a reliable experimental model of D.L.E. To what extent it may prove possible to reproduce D.L.E. in an animal species remains uncertain: the hypertensive rat responds to high doses of hydrallazine by the production *of glomerular lesions of a most unusual type* (personal observations, unpublished), but as with the dog it cannot be held that these resemble the lesions of D.L.E. in more than the most superficial manner.

Pathology Department,
University of Edinburgh.

DUGALD L. GARDNER.

CORTISONE AND ULCERATIVE COLITIS

SIR,—Mr Brooke[9] is right in saying that it is rare to find the large intestine adherent in uncomplicated ulcerative colitis, but we wonder if it is correct to attribute the other effects he speaks of entirely to steroid therapy. By their anti-inflammatory action steroids may sometimes predispose to friability and disintegration, but the state of the bowel may be the result simply of using ineffective therapy of any kind too long and/or allowing the disease to advance beyond the possibility of surgical help. That the condition Brooke describes may be due to the disease itself is illustrated by the following case-history.

A woman aged 34 was admitted to hospital ill, toxic, and incontinent of fæces, with a five weeks' history of severe ulcerative colitis. The only treatment received had been a short course of (?) chloramphenicol at the onset.

At sigmoidoscopy numerous deep excavating ulcers were seen, baring the muscle coat. Four days after admission, after two days' treatment with oral neomycin, colectomy was carried out by one of us (J. S.). At operation the colon was very friable and several perforations had occurred in the descending and sigmoid colon where the bowel lay against the anterior abdominal wall. There was no frank peritonitis. Extensive peritoneal fæcal soiling occurred from disintegration of the friable bowel during its removal. Most of the mucosa below the hepatic flexure had disappeared. The patient made a rapid and uninterrupted recovery, leaving hospital 43 days later. The neomycin may have been responsible for the absence of peritonitis although colonic fæces cultured at the operation were not completely sterile.

We agree that steroids should always be used with caution in ulcerative colitis, and we have never given them to patients with ulcers extending down to the muscular coat. This type of ulceration must be looked for, and can be seen easily on sigmoidoscopy and (perhaps less easily) on radiography. Brooke's comments and illustrations of the X-ray changes in severe cases are of great interest and importance. In patients with this type of deep ulceration we find that colectomy carried out promptly is better than any form of medical treatment. A short preliminary course of broad-spectrum antibiotic by mouth is justifiable to reduce infection in case of perforation.

In the Medical Research Council trials of steroid treatment in ulcerative colitis it has been clearly understood that the length of the course of treatment was governed by the patient's condition. Whether the trial treatment is continued for the full six weeks has always been decided by the physician in charge of the patient. Brooke says that steroid therapy should cease if there has been no response after one or two weeks. We have not found this necessary, and indeed it is common experience that patients may take much longer to improve with any medical treatment. What is needed is close observation, including repeated sigmoidoscopy and radiography, of the patient who shows signs of clinical deterioration. In this way deep ulceration may be discovered and surgery resorted to in time.

CARDIAC ARREST

SIR,—I was surprised to read in your annotation under this heading[1] the statement that the use of cardiac massage is restricted because a physician and even a general surgeon may hesitate to do an immediate thoracotomy. This sentence seems to indicate some confusion of thought. The restriction surely applies only to the ability or knowledge of the physician or surgeon and not to the use of cardiac massage. One would not expect to see an annotation headed "Laryngeal Obstruction" in your columns which contained the statement that the use of tracheotomy in the treatment of this condition was restricted because doctors might hesitate to perform it. The two situations are precisely analogous.

I fear that your annotation might encourage doctors in their hesitation to perform thoracotomy and might lead them to attempt the alternative methods which you outline. This could only have the effect of increasing the mortality from cardiac arrest which is still about 70%. In fact, several hundred people die from this condition every year.

The immediate essential in the treatment of cardiac arrest is not to re-start the heart but to maintain the cerebral circulation. As you state, an external electric shock *may* restore normal ventricular action. Cardiac massage always *will* maintain effective cerebral circulation, but it must be started immediately without recourse to other methods as a preliminary.

The time has now come when all, including physicians and general surgeons, who carry out any procedure on a patient which may cause cardiac arrest should be capable of dealing with the situation by thoracotomy and cardiac massage. Such procedures include local and general anæsthesia, injections, and investigations as well as operations. I have personal knowledge of cases in which physicians have performed cardiac massage and in which anæsthetists have had to persuade surgeons to open the chest and even, when the surgeon refused, have had to perform a thoracotomy themselves.

I do not think the position was put too strongly by Beck[2] when he stated:

> "I don't think we are doing the right thing for our patient unless we have knowledge of resuscitation procedures. I think it is a crime for a surgeon to walk away from the operating table, the patient dying, without doing anything. If I were on a jury in a court and had to make a decision about the responsibility for the death of a patient with a previously normal heart who died on the operating table, I would have to vote against the surgeon. There is no excuse, it seems to me, for a surgeon not knowing how to resuscitate a heart."

Brompton Hospital,
London, S.W.3.

B. B. MILSTEIN

THE USE OF PLASMA

SIR,—Some of the contentions with regard to plasma and its substitutes in Admiral Ramsford's letters of Oct. 27 and Dec. 15 should not be allowed to pass unchallenged. While his initial suggestion that homologous-serum jaundice should become a notifiable disease is one with which few would disagree, several of his subsequent statements are, to say the least, extremely controversial.

With regard to the risk of homologous-serum jaundice following plasma-infusion, Dr. Wallace (Nov. 3) has provided the correct figures and drawn attention to the view that modern plasma preparations can be used with relative impunity in this respect. Coagulation defects due to the citrate content are likely to be encountered only with massive transfusion in the presence of liver failure. The risks of dextran infusion are less clear, though there is increasing evidence that it may on occasion precipitate coagulation failure.[1]

The statement, however, that stored plasma is of no value in correcting coagulation defects is seriously misleading. It has been shown that dried plasma stored at room-temperature for three years has a high fibrinogen content.[2] This is the most widely available plasma preparation, and when infused in concentrated solution it has proved life-saving in cases of coagulation failure due to fibrinogen depletion. Deaths have occurred in such cases while attempts were being made to obtain fibrinogen from a distant source, while the immediately available crude plasma was ignored. It would be most unfortunate if Admiral Ramsford's remarks should lead to further tragedies of this nature.

Department of Obstetrics and
Gynæcology, University of Liverpool.

JAMES S. SCOTT

THE SCIENTIST AS CITIZEN

SIR,—Although it is highly relevant to medicine, Dr. Douglas McClean's paper[3] is concerned with a wider than medical issue.

Where scientists are concerned, I must confess that I belong to the ivory-tower school and believe that professionally they should, in Dr. McClean's words, only speak when spoken to. By this I mean that, while they have every right and capacity to advise about means to ends, *as scientists* they know nothing of ends themselves. In certain contexts they are most anxious to tell us so. They are rigidly anti-teleological in their attitude to discoveries in every field, and they remind us from time to time that they can discern no apparent purpose in the universe. They cannot therefore tell us what policies to adopt and what to reject in order to pursue universal ends, because no such things are known to them, nor have they any scientific criterion of what is "good." Our æsthetic sense (no doubt epiphenomenal) is offended by certain aspects of Nature, in plant, animal, and human existence, and we desire to avoid them because they are unpleasant to us and may deprive us of life, which we have an irrational urge to preserve; but as scientists can we say more than that according to our terms of reference?

The point which I think some scientists are apt to overlook is that science is a valid guide for only a small part of human experience, and those who want to increase its proportion do so by narrowing the field, as by ruling out many questions as unmeaningful, and not by extending its range. Dr. McClean, for instance, has in mind a number of objectives which he thinks scientists should act in concert to secure, such as the abolition of war, the avoidance of over-population, and the development of agriculture. But it is as citizen, not as scientist, that he has learned to regard these as worthy aims, contributing to a happier and more secure world that is a desirable goal not only to the humanist tradition The ideology to which a scientist subscribes—humanist, Christian, Communist, or what not—ought not to colour his observations of natural phenomena, but it seems to me that it is bound to determine how he applies his knowledge of them He serves some master or other in the employment of his talents, however much he might wish it otherwise

PREGNANCY TOXÆMIA

SIR,—Mr Norman Morris and his colleagues at University College Hospital have shown (Sept 8, p 481) that the blood supply of the pregnant uterus is diminished by exercise, and that in toxæmic women the blood-supply is below normal even when the patient is at rest I warmly welcome this new evidence, but its great obstetrical importance cannot be fully appreciated unless it is related to other clinical and experimental data May I therefore give my explanation of the findings ?

In the toxæmic woman at rest, diminution of uterine blood flow is due in the first place to a mechanical factor—namely, tautness of the uterine muscle (Reynolds[1] has emphasised the tautness of the uterine wall in first pregnancies and has also shown that this diminishes the myometrial circulation[2]) But resistance to stretch, as seen in the virgin uterus or in one which has to enlarge abnormally to accommodate a big infant, twins, hydramnios, or concealed accidental hæmorrhage, also sets off the uterorenal reflex,[3] and this induces a variable vasoconstriction in the kidney, dependent on the strength of *the stimulus and the responsiveness of the kidney to it* Renal ischæmia in its turn induces a corresponding degree of splanchnic vasoconstriction,[3a] which (since the uterus lies in the splanchnic bed) further impairs the uterine *circulation*

Exercise, whether in the normal person or in the toxæmic patient, also induces vasoconstriction in the kidney In a normal person, exercised to the point of *discomfort, the flow of plasma through the kidney may* be reduced by a third[4] This effect is likewise evident in renal disease, for we know that in a patient with acute nephritis in whom the glomerular filtration-rate and the effective renal plasma *flow are already diminished*,[5,6] these will be further reduced even by the small effort involved in becoming ambulant after being in bed[7] Similarly in women with pregnancy toxæmia the renal plasma flow has been diminished by the uterorenal reflex, and, where renal ischæmia resulting from this reflex has been acute or long-continued, it will have caused glomerular swelling and exudate in Bowman's capsule,[8] further *diminishing* the renal *circulation* (Experimentally, similar anatomical changes have been provoked by ischæmia in the studies of Hoff,[9] Fajers,[10] and others) Exercise or effort, by increasing renal ischæmia, will increase *this damage* As *Morris* and his associates say, in pre eclampsia

> " the blood flow to the uterus is still sufficient for fœtal needs in spite of further reduction caused by maternal activity In the *extreme case however, the additive effect of reduction* of uterine blood flow by exercise and that dependent on the pre eclamptic vasoconstriction might endanger the growth or viability of the fœtus "

The physiological value of the renal-ischæmia mechanism is that it diverts oxygenated blood from the kidney to other parts of the body where such supplies may be particularly needed In exercise it increases the flow of blood to the muscles and in shock it maintains the flow to the brain Though the pregnant uterus stands to *gain by this diversion of blood associated* with renal ischæmia, it loses by the vasoconstriction which renal ischæmia induces throughout the splanchnic bed, and on balance it loses Considered teleologically, the deficiency of *circulation caused* when *the uterus resists stretch* could be the ultimate stimulus provoking the uterorenal reflex, and continuing deficiency in the blood supply to the uterus would keep the uterorenal reflex in action, *and increase renal ischæmia—the vicious circle suspected* by Morris Thus the defensive physiological mechanism may be so intense as to destroy the fœtus (by anoxæmia) and even the mother (by interfering with renal function *and by inducing hypertension and fits)*

In the uterorenal reflex we have the primary explanation of pregnancy "toxæmia" and its consequence Hitherto the chief evidence that there is such a reflex has been (1) that in animals blanching of the kidney has been seen to follow distension of the uterus, and (2) that in pre eclamptic women tocometric *tracings* in labour have—on one occasion so far—shown that heightened uterine tone precedes *hypertension* (presumably renal)[11] Also the satisfactory therapeutic effect of draining the liquor has frequently been reported But now there is also biochemical evidence, for McGaughey et al[12] have demonstrated, *in dogs, a mean reduction of* 23% in the urinary clearance of *p* aminohippuric acid following acute distension of the uterus—indicating a reduced renal plasma flow (I must add that these workers *do* not themselves *attribute* this change *to* renal cortical ischæmia, nor do they yet accept my interpretation of its part in the ætiology of toxæmia)

The University College Hospital investigators have not only provided a rational explanation of the benefit of rest to the toxæmic patient they have advanced our insight into the ætiology All their findings are compatible with the view that pregnancy " toxæmia " results from renal ischæmia induced, *through the* uterorenal *reflex*, by stretching of the resisting uterine muscle

London W 1 JOHN SOPHIAN

SHORTAGE OF RADIOGRAPHERS

SIR,—You are doing a service by calling attention to the shortage of radiographers, but I do not think you or Mr Baxter (Dec 22) are correct in assuming that this is primarily due to inadequate remuneration This dissatisfaction is largely confined to the few male radiographers

The shortage of entrants to diagnostic radiography is due to a variety of causes *The radiation hazard* you mention does deter some but not very *many* The other factor you mention—namely, the age of entry—is important for the reason you state This difficulty can be overcome *in some measure by offering* suitable candidates posts as dark-room technicians until they reach the required age of entry

The educational requirements before *a* girl is accepted as a trainee are *altogether* too high and the course itself should be completely revised The knowledge of physics and apparatus construction required by the syllabus is ridiculous In the old days, maybe, a radiographer was required to tinker with a faulty set, but nowadays no radiographer would be permitted to touch

the "works" under any circumstances An abstruse knowledge of circuits, transformers, timers, stabilisers, &c, is therefore not required

Another hindrance to training is the fact that students must be attached to an approved school, though it may be granted that with the present syllabus it would be very difficult for a girl to pass the examinations without lectures from physicists

Since the N H S began, radiographers in hospitals must have the M S R qualification It is at once evident that the Society of Radiographers is in a powerful position and by making the examination far too difficult limits entry into the profession

The taking of a good radiograph consists of two essentials (i) positioning of the patient, and (ii) correct exposure of the film For neither of these is a knowledge of physics, mathematics, or English language essential Any intelligent girl of 17 or 18 with an aptitude for the work could be taught to do all that is necessary in twelve to eighteen months of practical training in a large and busy department

I must disagree with your suggestion that more superintendents should be appointed It is only in very large hospitals that a superintendent is required The radiologist in charge is automatically the superintendent

My own view is that radiography is essentially a job for a girl There is insufficient scope to give permanent satisfaction to most men I would be the last to decry the value of a first-class male superintendent and I think that male students should be very carefully selected with this ultimate objective in view

X Ray Diagnostic Department
General Infirmary Leeds
G H ILLINGWORTH

SIR,—In your annotation on this subject[1] you cite the top salary for a chief laboratory technician as £1025 This figure applies to chief technicians with a staff of twenty technicians, of whom there must be very few The top figure that the great majority of chief technicians can expect to obtain is £900 per annum

X RAYS AND LEUKÆMIA

SIR,—Unlike Dr Rabinowitch (Dec 15) I would congratulate Dr Stewart and her colleagues on the evidence they have brought forward, which has already induced a caution in the requests for multiple X ray investigations

In 1932 I showed that in osteochondritis it was possible to see from radiographs the state of the bone and this permitted radiographic control of the treatment, though little change might be registered on radiographs taken at intervals of less than six months[2] Since then radiographic control has been extensively employed, particularly in chest and fracture work—in both of which I have seen as many as 100 films of a case I have seen patients who for one reason or another have been transferred for treatment to as many as six different institutions At each an X-ray investigation has been done, though the radiographs and reports of the former examinations have been available and the initial report later proved accurate Surely such repeat examinations involve unnecessary exposures and reveal a very unfortunate failure to respect the opinion of colleagues? This is apparent to the patients The multiplicity of repeat examinations for "radiographic control" actually does more harm than good to the patients since the intervals between them are so short that little or no change is registered, and the report "no change" must have a depressing influence on the patient No case with such multiplicity of radiographs has developed leukæmia to my knowledge

As an experienced radiologist who desires to give the best help he can to his patients and colleagues, I welcome any evidence, such as that produced by Dr Stewart and her associates, which will cause people to think before they demand of very hard-pressed departments multiple expensive examinations, or administer chemical or physical agents which may do more harm than good —fully acknowledging our ignorance of the possibilities

Birmingham
JAMES F BRAILSFORD

PSYCHOTHERAPY IN GENERAL PRACTICE

SIR,—That psychotherapy in general practice should be the subject of a leading article in your journal (Dec 29) suggests that it has at long last arrived, but your remarks were limited to the use of psychotherapy in general practice for patients with psychoneuroses Unfortunately this is only part of the story since psychoneuroses, according to various authors,[1-8] account for only 6–16% of all patients seen When we take into consideration those patients suffering from psychosomatic conditions (or stress disorders) the incidence rises considerably In a survey[4] in my practice the incidence was 42 8%, and Pougher[9] found that 47 6% of all consultations were sought by patients with some form of neurosis (including psychosomatic conditions)

For those who fear that physical disease is being misdiagnosed as neurosis, I would mention that in an analysis of all patients referred to hospital over a period of three years, 31 3% were found to be suffering from psychoneurotic illness or stress disorder[10]

In my experience, the use of psychotherapy in general practice is by no means limited to patients with frank psychoneurosis there are many conditions whose labels disguise underlying neurosis, so that they do not appear in any survey showing the incidence of neurosis Patients with these conditions are, nevertheless, amenable to psychotherapy, either with or without other forms of treatment It is hardly necessary to name them for those experienced in general practice but, since few psychiatrists would have had such patients referred to them, I might mention some that I have recently treated with psychotherapy with satisfactory results duodenal ulcer, asthma, dysmenorrhœa, psychogenic menorrhagia, pruritus vulvæ, hypertension, migraine, neurodermatitis, and spastic colon

In discussing the use of psychotherapy in general practice with many colleagues, several have queried, for purely material reasons, the wisdom of my doing so It has been pointed out to me that the general practitioner obstetrician receives a special fee for his services, which may take up twelve hours of his time over seven or eight months Psychotherapy may take two or three times this amount of time over the same period without any fee over and above the capitation fee This makes it necessary to keep one's list down to a manageable level, otherwise there would be insufficient time to give to those patients requiring it The result is a self imposed limit to one's income

In addition, therefore, to your excellent suggestion that means must be found to improve teaching, means must also be found to provide proper fees for special treatment carried out by general practitioners

It is all very satisfying to look after one's own patients and to treat them oneself, but it is not possible to bring up a growing family on satisfaction alone This could well produce an unfortunate conflict, as the way in which the general practitioner is paid encourages him to cultivate a large list which must make it impossible for psychotherapy to be used for many patients This is more than regrettable since I firmly believe that it is by

psychotherapy more than any other method of treatment that more patients will be helped—not only for their existing illnesses but also as a form of preventing future ones in themselves and in their children

One last point you stated that almost every specialty began in a small way as part of the work of the general practitioner May I say that I sincerely hope that psychotherapy does not become a specialty but remains essentially a method of treatment to be used by the general practitioner in general practice

London N W 3 **PHILIP HOPKINS**

TREATMENT OF BURNS WITH PLASMA

SIR,—In the burns unit of this hospital we have been treating acute scalds, and some burns suitable for exposure, by painting them with concentrated reconstituted human plasma (1 gramme dried plasma to 5 ml Tyrode fluid) and then drying the area with a hair-dryer modified to filter the air This treatment is repeated once 6 hours later A crust is formed after 16–18 hours and becomes strong after 36–48 hours Whenever possible, depending on the extent of the damage, the area is immobilised with plaster-of-paris, to assist in the healing process

We are now going ahead with full clinical trials

DELIRIOUS PSYCHOSIS DUE TO MEGIMIDE

SIR,—May I make three comments on Dr Kjaer-Larsen's report[1]?

(1) The contradiction presented by the absence of "'Megimide' psychosis" among the patients reviewed by Gershon et al[2] and the frequency of this psychosis described by Kjaer Larsen I have treated only two comparable cases (neither of whom showed post treatment psychosis) and therefore I cannot comment directly, but in 1947[3] I recorded an outbreak of atropine poisoning associated with barbiturate narcosis and said "the conclusion can hardly be escaped that the narcotic not only masked the action of the atropine effectively, but also in some way reduced its excretion, so that at the end of treatment an effect was rapidly produced as if something like the total atropine given was acting as a single dose" (About 30 mg had been given over 10 days) The "atropine psychoses were practically identical with the "megimide psychoses" described by Kjaer Larsen both in character and in the time of onset relative to the barbiturate intoxication, and I wonder whether his patients could have taken hallucinogenic drugs such as mescaline, Indian hemp, or even amphetamine[4] shortly before the overdose of barbiturate

(2) Kjaer-Larsen describes, but does not classify, three kinds of hallucinations (*a*) lights, flashes, figures, colours, &c (to which might be added certain noises, smells, &c), (*b*) whole scenes (to which might be added intelligible scraps of conversation, associated smells, &c), (*c*) experiences inseparable from ideas (e g, of persecution) which are difficult to separate from delusions and are often supported by illusions and false interpretations It is a temptation to interpret these, in the case of visual experiences, for instance, as successively occipital, *temporal* and frontal brain phenomena, but at any rate some such classification should be kept in mind Further, each of these three kinds of phenomena may be straightforward sense experiences or abnormal distortions This is clearest in the case of (*b*) a scene may be an identifiable memory or a bizarre impossibility With (*a*) and (*b*) especially, unusual intensity is conceivably a 'release phenomenon

(3) Once again a case is reported of a schizophrenic who had no difficulty in recognising his vivid experiences as something apart from his long standing illness a common although not uniform finding in schizophrenics who are given hallucinogenic drugs and one comparable to the insight retained by the patients with temporal lobe lesions described by Penfield and Jasper[5] I have treated two schizophrenics who were sensibly perplexed by such phenomena for about a year before the ultimate diagnosis could be made—i e, before there was any failure to assess the abnormality as such and before any kind of delusion was manifest

St Ann's Hospital
Canford Cliffs Dorset

D N PARFITT

VACCINIA AS A POSSIBLE CARCINOGEN

SIR,—I have seen five cases of malignant disease arising a few weeks after smallpox vaccination

CASE 1 (previously reported[1])—A girl, at puberty, was vaccinated on the left thigh 3 weeks later a sarcomatous mass appeared in the right ischiorectal region It soon metastasised to the superficial lymph nodes and liver The child was dead 3 months after the illness began

CASE 2—A 44 year old soldier was revaccinated in the left deltoid region in 1942 A few weeks later he had enlargement of the left axillary lymph nodes, which became matted together The surrounding tissues were infiltrated Biopsy showed that the condition was a lymphosarcoma

CASE 3—A European woman of 65 said that she had been vaccinated in infancy, but there were no obvious scars She was revaccinated in the left deltoid region 2 weeks later the left axillary lymph nodes became enlarged, followed by the right axillary nodes and the inguinal nodes on both sides; an abdominal mass could be felt Biopsy of a lymph node showed lymphosarcoma

CASE 4—A European, aged 51, had been vaccinated in infancy He was revaccinated in the left deltoid region 3–4 weeks later he developed a lymphosarcoma, diagnosed by biopsy, in the left inguinal glands

CASE 5—A European, aged 58, developed abdominal pain 2 months after vaccination 2 months later he had a partial intestinal obstruction At operation a lymphosarcoma of the transverse colon was found, with involvement of the mesenteric nodes

I have seen all the last three cases this year Two others bear on this question

CASE A—Rea[2] reports a case of squamous carcinoma in an African woman aged about 40 It arose on a vaccination scar very soon after inoculation The vaccination in this case was apparently a primary one Dr Duran Reynals, of Yale University, has told me that he knows of cases in which epithelioma appeared after revaccination

CASE B—A child, aged 5 years, had a tumour of the left thigh which was diagnosed as a metastatic neuroblastoma At first it responded very well to radiotherapy, but later it became resistant The boy was then treated with 'C B 1348, an oral preparation of nitrogen mustard, and seemed to respond to this for a while, but after 2 months there was severe leucopenia and the drug had to be stopped 2 weeks later he had a generalised vacciniform eruption, with umbilicated vesicles which came out in crops and eventually covered the whole body There was a swinging pyrexia At this time the tumour appeared to spread more rapidly Vaccinia virus wa isolated from the fluid of the vesicles He had been vaccinated in infancy

The lesion produced by vaccination is usually only local, but the virus is disseminated throughout the body It has a special predilection for tissues of the reticulo endothelial system In 1952 Duran-Reynals[3] published a study of the dual rôle of certain viruses, which can act as cell stimulants or cell destroyers, depending on certain environmental influences of which age is of primary importance He also described experiments which showed that when a carcinogen, methylcholanthrene, was applied to the skin of fowls, a latent pox virus was activated, and that this virus could be recovered from the various neoplastic diseases which appeared when treatment with the carcinogen was continued

In most of the cases reported here the patient was over 40 This is interesting because in his experiments on birds Duran-Reynals found that the age of the host was of primary importance in deciding whether a virus

THE FAMILY DOCTOR

SIR,—Many extraordinary statements have been made in 1956, but there were two in particular which I find amazing beyond belief The first was the astounding announcement that the average practitioner receives £2222 per annum after he has paid his expenses, to an average Scottish practitioner this would be frankly laughable were it not for the damaging impression that it has given to the lay public The second, and perhaps more astonishing news appeared in your annotation last week, where we learned that a practitioner with 4200 patients "at risk" (a delightful phrase, I always think!) spends an average of 30 hours a week "in contact with patients, travelling between them, and administration," as established by stop-watch I cannot help wondering if the good doctor's stop-watch was slow, because I find myself spending not less than 48 hours in any week looking after about half the number (without too much risk, I trust) Nor can I accept that my organisation is at fault I do not need a stop-watch to confirm these facts, because for sheer, solid blocks of time in the day I simply never cease from "contact with patients, travelling between them, and administration"

The combination of these two extraordinary statements would suggest that the G P is grossly overpaid for a very leisurely job I would like to see much wider publicity given to an equally unbelievable fact which, however, is all too true, that for looking after each member of the demanding public for a year the practitioner receives about 5*d* a week regardless, from which he must meet *all* his expenses This is the root of the tragedy, it can be proved inescapably that from this simple fact all the evils of the National Health Service arise, from the destruction of the family doctor to the overwrought outpatient clinics, from the overwork among some of us to the sad fate of our colleagues who cannot find established employment

To revert to the personal I would say that without my few pleasant, appreciative private patients I would have neither the means nor the desire to survive in general practice

DYSPHAGIA

MEDICINE AND THE DRUG INDUSTRY IN GERMANY

SIR,—During a recent visit to Germany I learned of one significant aspect of the relationship between doctors and drug manufacturers that has not been commented on by your contributor in his most interesting article[5] Apparently there is an excess of doctors in that country, and vast numbers are unemployed As a result, the drug houses have no difficulty in persuading qualified practitioners to act as their representatives, and something of the order of two and a half thousand doctors are so employed, one company alone employs 250 for itself, a further 200 for its smaller subsidiaries, and the same number again for one of its American associates

These doctors do not actually sell drugs, they visit practitioners frequently, discuss various clinical matters with them, and notify them of new drugs that their company is marketing If the doctors show interest, the sales division then sends samples I was amiably escorted by one such representative on a recent fact-finding visit, as might be expected some practitioners were extremely friendly and helpful and were obviously pleased to see him, others treated him like a black sheep I made inquiries later both from his sales colleagues and from practising doctors and found that both groupings tend emotionally to regard these doctors as inferior, although objectively both realise that the unemployment-rate is so high that such a stigma must be, for the most part unjustified However, the situation is now so deeply ingrained that this enormous diversion of clinical training from bedside practice to commercial sales promotion has come to be regarded as normal amongst all but the eldest members of the profession

SAEGESSER'S SIGN

SIR,—I was interested in Mr Heslop's description (Dec 8) of Saegesser's sign—particularly in the statement that pressure over the phrenic nerve in the neck causes pain in the abdomen, even in its lower quadrants The fundamental fact for understanding the mechanism of any localised subjective experience, such as pain, is that it depends upon the activity of cerebral cells rather than on the activity of peripheral ones[1-3] Therefore it is unlikely that Saegesser's suggestion, that the secret lay in "the fact that the phrenic nerve carries sensory fibres from the capsule of the spleen," is the correct one, because, the afferent impulses, having circled round through the cœliac plexus to enter the phrenic nerve, would presumably share the common neurone pool of the other phrenic fibres in third and fourth cervical segments of the spinal cord The site of the subjective experience depends on the central connections of this cervical neurone pool, irrespective of their topographical origin, and would therefore, be referred to the "shoulder tip" even though they originated *in* the spleen

A further objection to Saegesser's explanation is that the necessary neuronal meandering, though possible, is hypothetical, no connection between the splenic plexus and either the left or right phrenic plexuses being mentioned by Mitchell,[4] Moreover it should be recalled that one of the features of referred shoulder-tip pain of phrenic origin which puzzled Lewis[5] was that the reference was always to the superficial structures and never in the reverse direction, and in my own experiments stimulation of the phrenic nerve in the neck of conscious patients never produced abdominal pain

Hoffman's account of the mechanism seems to be more hopeful, because it is very easy to activate the motor fibres of the phrenic in the neck, and the sudden contraction of the appropriate half of the diaphragm makes the conscious patient jump Such a contraction of the diaphragm could easily rub some of the blood clot across the costal margins of the diaphragm, and, as the diaphragm here has an intercostal nerve-supply, this could easily cause pain referred anywhere in the territory of D7–D12 inclusive Mr Heslop is, I think, correct in suggesting that the mechanism of this sign depends on the double sensory innervation of the diaphragm, but pain in the peripheral distribution of the intercostal nerves could not be produced by any flood of sensory impulses up the phrenic nerve, however strong it could be produced only by a contraction of the diaphragm, due to the motor fibres in the phrenic, exciting traction on the costal margin of the diaphragm, where the muscle and covering peritoneum are innervated by the intercostal nerves A year ago when I had a pneumonia in the left lower lobe, I noticed that any deep breath regularly produced pain in the tip of my left shoulder and in the left upper-abdominal quadrant, and

that it occurred with inspiration, but I confess that I did not compress my phrenic in the neck as a separate test

If Mr Heslop will agree that the link between the pain in the shoulder and the pain in the abdomen is the stimulation of the motor fibres in the phrenic by the digital pressure in the neck, causing a contraction of the diaphragm, I think his explanation can be accepted

INJURY BY ENEMA SYRINGES

SIR,—I read with interest the report by Mr Large and Dr Mukheiber[1] and I should like to describe a further case

Five years ago a very fat man, aged 60, was brought to the university clinic of therapeutics with slight abdominal distension and severe lower abdominal tenderness and rigidity He said that twelve hours before, because he was constipated and was feeling ill, he had decided to have an enema He was in his garden, and he thought that the irrigation pump would be suitable He inserted the hard nozzle of it, and water was forcefully injected without the aid of any other person There was no evacuation of the bowel, but immediately he began to have lower abdominal colic, mild at first but gradually becoming more severe, and which was succeeded a few hours later by continuous abdominal pain At laparotomy a wide perforation just at the pelvirectal junction was found *The patient died a few hours later*

Athens
G E PAPAYANNOPOULOS

A SIMPLE SELECTIVE TEST FOR NURSES

SIR,—Mr Roberts (Dec 29) appears to have misunderstood my letter, the test was offered as a supplement to the more essential selection tests of intelligence and personality, not as a complete procedure in itself One would be temerous indeed in offering a single test in this rôle

What exactly does he mean by requesting a correlation for *each* student? Intrapersonal correlation coefficients, obtained with cattellian P technique, are unsuitable for relatively stable factors such as intelligence and reading ability Correlations for specific groups of nurses have been worked out 16 years ago by Professor Hunt,[2] who has shown *that reading comprehension correlates more highly with* examination results than any other test of this type—that is that presupposes no previous knowledge of the subject or previous scholastic attainment other than in language The rationale for such a test has been well formulated, the justification for its use rests solely on experience, the bar at which every selection procedure must stand trial

Mr Roberts's criticisms are on the whole irrelevant to the stated purpose of the test It makes no attempt to measure memory efficiency—this is better accomplished with a well standardised test such as the Wechsler memory scale Neither does it measure "writing fluency"—indeed, it has been specially constructed to eliminate this factor Most authorities differ from Mr Roberts in believing that writing fluency is a poor predictor in this field As Professor Ballard[3] says "it is egregiously bad as a basis of measurement It fails through its very wealth and complexity It confuses the examiner by telling him too much, and diverting his attention to irrelevant merits and defects" The test measures, inter alia concentration, but not as a separate quantitative factor Does your correspondent really expect such refinement in a preliminary test?

The mean difference of 1 quoted by him is quite meaningless (with or without the S D) unless one knows the group means for without these one cannot determine the statistical significance of such a difference

These are early days for nursing selection techniques—a period of trial and error, refinement, and modification, which will extend into the future for many years to come It is healthy—for test devisers in particular and the profession as a whole—that procedures should be challenged and criticised, for these are the spurs to progress, which comes to those humble in the face of their own inadequacies The greatest obstacle is surely the complacency expressed in the opinion that "the most efficient method" is one's own

Parliament

A New Pattern for Dental Practice

ON Dec 21, shortly before the House of Commons rose for the Christmas recess, Mrs EVELINE HILL drew attention to our woeful shortage of dentists She wondered what would happen if all the expectant and nursing mothers and young children sought the dental treatment to which the health service said they were entitled for there were not enough dentists to go round A further difficulty was that about half of our 16,000 dentists were over middle age and would retire before 1966 Yet recruitment at present was not more than 650 a year The trouble was that there were too few places in the dental schools She believed that we needed 1000 places for new students each year

Miss PATRICIA HORNSBY-SMITH, replying for the Ministry of Health, readily agreed that we were short of dentists Though we had about 15,000 dentists on the Dentists' Register, only 14,000 lived in the United Kingdom That meant that there was only 1 dentist to every 3278 of the population, which was lower than in Canada, Sweden, Norway, or the United States Unfortunately we were now about to experience the results of the small entrance to the dental schools in earlier years and we should be losing all the dentists who took advantage of the 1921 Act and were now reaching retiring age But there had been a steady *improvement in the intake into the dental schools* in the past three years, and the schools were now practically up to capacity The possibility of attaining within the next ten years the 20,000 dentists needed to provide a really adequate service would clearly depend on the public demand, the effectiveness of dental health education, the proportion of dental skill which was applied *to the priority classes, the contribution* which ancillary workers could make, the development of fluoridation, diet, the extension of dental research, and the better organisation of the profession

The McNair Committee had recommended an annual intake of 1000 students But the dental schools had only 645 places, to provide another 350 places would raise *problems of capital expenditure and staffing* Another problem would be to get enough students of the right calibre In the past few years some applicants had lacked the necessary educational qualifications for the course The McNair Committee had come to the conclusion that the main reason for the shortage of dental students was the public's lack of recognition of the true *importance of dental health* As a result the profession did not enjoy the status which it merited Parliament had this year taken a big step towards improving the status of the profession by giving it self-government by the establishment of a General Dental Council But many of our present difficulties were due to the organisation of the profession

The preponderance of single-handed practices resulted in high overhead costs, a lack of opportunity for the dentist to concentrate on the work at which he was most apt, and a position in which the skill and experience of the older dentist was often not adequately used and which *failed to compensate for his growing inability* to work as long or as speedily as his younger colleagues This structure of the profession largely caused the peculiar pattern of earnings, which dropped considerably from middle age onwards The skill and experience *which came from a lifetime of practice should be recognised in the remuneration of a dentist if in fact he was* applying that skill and experience and not spending his time on the more routine type of case which could be dealt with as ably and more speedily by his junior Outside the hospitals and clinics the answer seemed to lie in group practice She suggested that the dental team of the future might consist of one member whose special interest lay in preventive dentistry and the care of children, another whose forte was conservative technique, another who had specialised in oral surgery, and another who had made the provision of dentures his specialty, all of them working under the leadership of the senior member of the firm, a man ripe in experience and diagnostic ability Such a team, backed by the skilled services of a dental hygienist and a dental technician, would, she believed, go far to satisfy the professional aspirations of the young dental man and woman of the future The time had perhaps come for the profession to give serious thought to the advantages which would lie in the introduction of group practices of that kind

Obituary

WILLIAM GEORGE BARNARD
C B E, F R C P

SINCE the war, in times which were at first difficult and which never became easy, Professor Barnard had been dean of St Thomas's Hospital Medical School and treasurer of the Royal College of Physicians In both offices he became responsible for war-damaged buildings, and, when material repairs were successfully completed, the start of the National Health Service gave rise to problems of administrative reconstruction To these tasks he brought judgment, ability, and an enthusiasm which was always turning his mind to plans for the future

He was born in 1892 in Tangier, where his father was a missionary, but on his father's death the family returned to Bath His medical studies at the London Hospital were interrupted by the 1914–18 war, during which he served in France with the Royal Field Artillery He came back to The London to captain the rugby XV and to qualify in 1920 Soon after qualifying he went to work in the pathological institute under H M Turnbull and became junior assistant director There he acquired the thoroughness and insistence on accuracy in observation and description which characterised his work as a pathologist

[Elliott & Fry

From The London in 1923 he went to A E Boycott's department at University College Hospital In 1927 he spent some time at Freiburg as a voluntary assistant in Aschoff's laboratory In 1931, however, the London County Council formed a pathological service for their newly acquired hospitals, and Barnard was one of the first pathologists appointed His task was to start the Central Histological Laboratory at Archway Hospital, the only one in the service entirely devoted to morbid anatomy and histology He set himself, with enthusiasm and tact, to bring home to all the doctors who could use the laboratory the value of reliable and comprehensive investigations in these branches He won their confidence and that of the administrative staff at County Hall, and in eight years he had created from nothing an active smooth-running laboratory with a staff of four pathologists and a fine museum It was organised so as to make the wealth of material from an almost virgin field easily available for research and he never ceased to emphasise the importance of this and to encourage it

Of his years at Archway Hospital A B B writes

"Barnard expected a high standard from his staff, but trusted them to give of their best, backed them loyally, and worked hard for their advancement it was a happy and enthusiastic lab To have taken part under his leadership in the development of the Central Histological Laboratory was a great experience"

In 1939 he was appointed to the chair at St Thomas's His first years there were spent against a war-time background of disorganisation and improvisation, and when he became dean in 1945 he realised that he would be steering the school through a period of administrative activity He immediately collected it together under one roof in London—a courageous but vital decision at a time when there were fewer than 200 beds available in St Thomas's He successfully guided it through the intricacies of the National Health Service Act and put its future administration on a sound basis With more money for education and increased departmental staffs, he was conscious of St Thomas's lack of accommodation, and he never lost sight of his cherished project to rebuild the school Despite these many activities he found time for his own department, which ultimately covered all the pathology of school and hospital

Of late years his shrewd judgment and administrative ability had greatly increased his work outside the hospital His main outside interest was perhaps his duties as treasurer of the Royal College of Physicians, to whose fellowship he had been elected in 1938 The finances of the college benefited from his discriminating supervision and its fellows' dinners from his interest in food and wine, his attention to culinary details, and his friendly presence He also sat on Government committees He had only a few months ago become dean of the faculty of medicine of London University As a chairman he was outstanding—firm, kindly, speedy His constant mastery of an agenda showed the thoroughness of his methods In 1953 he was appointed O B E

But St Thomas's was the centre of his work and there " he ruled as a benevolent autocrat "

Barnard (A L C continues) was essentially shy and reserved and he was undoubtedly held by many in considerable awe, but no student in difficulty or staff member with a worthwhile project ever left his office without help and encouragement In consequence more and more people turned to him with every sort of problem His inherent integrity, fair-mindedness, and high professional standing won him universal respect and affection Always a trifle remote from the students, he knew more of them than they suspected He appreciated the young and was proud of his flock Selection of students he regarded as a vital duty, and he was never absent from the chair of the interview board Realising that those with top academic brains can form only a small minority, he was happy to collect his share and then concentrate on character, personality, and versatility of achievement for the main body Artists and musicians were as valuable to him as rugger players and athletes His lean years as a student at The London gave him a real and understanding sympathy for the present impoverished generation No project for their well being ever lacked his support and he rejoiced in their successes—academic, sporting, or artistic His own wide interests aligned him with them far more than was realised, a good athlete in his youth, in later life his hobbies ranged from a considerable knowledge of old clocks and books to a keen appreciation of pictures

Never irritable or intolerant, he possessed a wonderfully equable temperament His working days, so full of abounding interests, had a solid foundation in a happy home life The tragedy of his death lies not only in the fact that he was achieving so much, but that delays beyond his control robbed him from seeing the new St Thomas's to whose future he gave such unstinted labour

In 1930 Professor Barnard married Margaret Roscoe Osler They had one son who is a house-physician at St Thomas's

A memorial service will be held in the chapel of St Thomas's Hospital at noon on Thursday, Jan. 17 A memorial service arranged by the Royal College of Physicians will be held at St Martin in the Fields on Thursday, Jan 31, at 3 P M

DOROTHY WOODMAN

M D, M Sc Lond

Dr Dorothy Woodman, lecturer in clinical pathology in the University of Bristol and consultant pathologist to Frenchay Hospital, died at her home in Bristol on Dec 21

She graduated B Sc in the University of London in 1917 and took honours in physiology two years later In 1921 she took the M Sc She joined the staff of the department of physiology at the London School of Medicine for Women and worked there for some years until she herself qualified in medicine from the school in 1931 After qualification she held resident appointments at the Royal Free Hospital, and in 1933 was awarded an A M Bird postgraduate scholarship in pathology In 1934 she took her M D She held a post as assistant pathologist at the Royal Cancer Hospital (now the Royal Marsden Hospital) in Fulham before she went to Bristol, where she was at first lecturer in pathology in the university Later she joined the department of preventive medicine as senior clinical pathologist, and when, under the National Health Service Act, she was transferred to the regional hospital board she retained, at considerable financial loss her association with the department She also helped to set up the clinical-pathology departments at Southmead Hospital and later at Frenchay Hospital and when that hospital was transferred to the regional hospital board she elected to remain there

R H P, who worked with her for many years, writ

Dorothy Woodman held a high standing in clinical patholog —not only in Bristol but in the whole country She will b remembered not only for her integrity but also for h stimulating help to many a young clinical doctor some o whom are today well known consultants She loved teachin and her students adored their teacher, but she detached hers from this academic field when she joined the preventi medicine department, and she often quoted this break as h one regret This feeling was often stirred anew when student continued to try and obtain her help with their work

The unexpected news of her death, arriving with h Christmas card and a friendly note, shocked us all with sense of irreplaceable loss This modest, shy, and friendl lady will be missed by all her friends—who were many

ROBERT CARMICHAEL

M B Edin

Dr Robert Carmichael, senior lecturer in pathology i the University of Leeds, died on Dec 19 He was skilled and mature exponent of the science of morbi anatomy, and the Leeds Medical School has lost a membe who will be recalled by many generations of medica students and by his colleagues with warm affection

After he graduated M B with honours in the Universit of Edinburgh in 1923, he held appointments in patholog in the university and Royal Infirmary and at the Roya Edinburgh Hospital for Mental and Nervous Disorders where he developed his special interest in neuropathology In 1931 he published his classical paper on the cerebra lesions in the chronic stage of epidemic encephalitis which was beautifully illustrated by the brush of his wife Soon after this he was appointed to the university department of pathology in Leeds, where, as lecturer and then senior lecturer, he spent the rest of his life At Leeds his research interests widened, especially in tumou pathology, and he was co-author of papers on adenolymphoma of the salivary glands and on metaplastic changes in the cervix uteri But he retained his first love for neuropathology, as was shown by his scholarly papers on the arterial lesions underlying cerebral aneurysms

F S F, who was already in the department of pathology when Carmichael came to Leeds in 1931, writes

We quickly became friends and the friendship deepened with the passing of the years Carmichael's outstanding characteristics were his innate modesty, his friendliness, and his sense of humour which had a delightful flavour all its own He never really hankered after a chair, this was partly on account of modesty, but perhaps mainly because he disliked the idea of having what he considered his real work interrupted by the claims of administration Yet three times he took charge of a department until a permanent incumbent should be appointed, and each time he gave unstinted time and effort to administrative duties, so that he was able to hand over his charge in a healthy, flourishing condition His last period as acting head of a department lasted for a little over a year and taxed his strength greatly, for it was during this period that his illness first manifested itself

R A W writes

Robert Carmichael's output of published work, excellent in quality though it was, is no adequate index of his contribution to the Leeds Medical School and to British pathology Whether in the post mortem room, in the museum, in the lecture theatre, or at his own laboratory bench, his work was done with systematic thoroughness and a palpable love for accuracy and truth He abhorred slipshod, hurried and untidy work of hand or mind, and he set an example of care and precision to colleagues, students, and technicians alike This was his greatest contribution to his subject—high standards of technical and scientific work, the artistry of pathology—and the more his former students and colleagues reflect on what he did and said with them, the more they will realise their indebtedness to him His colleagues both in and outside Leeds, often sought his help on their histological problems for no one was better able to give them a sound sane and helpful opinion They will long remember him, too for the humorous twinkle in his eyes, or the pithy comment or epigram with which he often resolved what had seemed a weighty question or with which he demolished pomposity or insincerity He had few interests outside his happy home life and his beloved pathology, which was his hobby For the greater part of his last illness, six months or more, he carried on his work as though nothing was wrong, indeed he worked until only a fortnight before his death, from an inoperable retroperitoneal tumour, which there is no doubt he himself correctly diagnosed some weeks earlier He was poised and smiling to the last

Dr Carmichael leaves a widow and a daughter

LORNA MURIEL ADELHEID GOULDEN BACH

M B C.S , D.P.H

Dr Goulden Bach assistant principal medical officer to the London County Council, died on Dec 26 She qualified from Westminster Medical School in 1930, and after serving at Westminster Hospital as house-physician and casualty-officer she took appointments at Queen Charlotte's Hospital and Battersea Maternity Hospital before joining the maternity and child-welfare and school health services in Barking, Essex In 1938 she was appointed an assistant medical officer of health for Wembley and during the late war she was responsible for the borough's refugees As assistant casualty officer for the area she was continuously on duty at night at the town hall

In 1946 she was seconded to the Ministry of Health as special assistant to the director of health services of UNRRA She was sent to do relief work in Athens, later she joined the antimalarial team in Macedonia The team also helped to establish public-health services under difficult and sometimes hazardous conditions, and Dr Goulden Bach was forced at one time to escape from bandits

In 1948 she was appointed as medical officer to the public-health department of the London County Council Her wide experience in public health and outstanding administrative ability were early recognised, and she was transferred in 1950 to the central staff at County Hall In 1952 she was promoted to assistant principal medical officer A colleague writes "Her capacity for establishing good personal relationships as well as her deep knowledge of child health made her advice valuable Her high courage in her illness was an inspiration and, at the same time, humbling to her friends"

Dr HUBERT WYERS

G F K writes.

Hubert Wyers's attitude to his specialty was never sectarian and he held strongly that "Medicine should not rest on any theoretical system of ideas, for once one part is discredited the whole is liable to suffer loss" Since he acted as adviser to several firms he was in a happily independent position which accorded with his temperament and enabled him to speak with authority on such diverse hazards as asbestosis and vanadium poisoning No doubt his earlier experience in industry also made it possible for him to see things in the factory from the point of view of people other than the doctor, he had no time for empire builders in occupational health and he had the firm opinion that doctors in industry only undermined their position as specialists in their own field when they encroached on the problems of the engineers or other specialists

Hubert Wyers was *simpático* to a degree and by many he will be remembered best as their friend however little they could aspire to his erudition and achievements He had had more than his share of anxiety and troubles one way or another but he never gave more than a hint of his difficulties, and there is no doubt that he was greatly sustained by his deep religious feeling which led him through Anglo Catholicism to be received quite recently into the Roman Catholic Church

---

Births, Marriages, and Deaths

BIRTHS

DIXON —On Dec 23 at King's College Hospital to Gabrielle wife of Dr W M Dixon M.R.C.P —a son Peter (a brother for Christopher)

Notes and News

SICKNESS BENEFIT FOR CERTAIN WIDOWS

CERTAIN widows who are not at present entitled to National Insurance sickness benefit will become eligible for it from Jan. 7, 1957 The widows who may be affected are those who in the past have drawn a widow's benefit but are no longer getting it and those who are now drawing a widow's benefit of less than 40*s* a week, including the widows on 10*s* contributory pension

Some widows may not be aware of this change Any practitioner attending a widow whom he considers to be incapable of work and who is not receiving sickness benefit or a retirement pension may like to suggest to her that she should inquire from her local National Insurance office to find out whether she is now entitled to sickness benefit

FOOD AND AGRICULTURE

THERE was no major change in the world food and agricultural situation in 1955–56 Agricultural production continued to increase and in all regions of the world was some 2 5–3% above the average of the previous quinquennium Estimates of the increase of populations varied from 0 7% in Western Europe to 2 4% in Latin America With the general food situation throughout the world for once stable, F.A O has devoted most of its annual report[1] to special factors influencing national and international trade

The main interest in the report is in economics In general, farm incomes have fallen and possible deterioration of the farming population in many countries must give rise to anxiety There appears to have been no corresponding fall in retail food prices The "marketing margins" have probably increased, in the U S A. the increase was 3% The basic dilemma of most governments is how to reconcile the dual responsibilities of maintaining the economic position of the farmers, at the same time providing consumers with adequate food-supplies at low prices

PHYSIOLOGY OF VOLUNTARY MUSCLE

A NEW number of the *British Medical Bulletin*[2] is devoted to the physiology of voluntary muscle The medical reader who is unfamiliar with such matters should not be discouraged, for, though he may not understand the details of what he reads he cannot fail to grasp the main points in each of these interesting articles Moreover, some of the remarks deserve attention because their meaning has application far beyond the *immediate context, for instance, A. V. Hill comments* that it is never safe, because one sees a particular need, to assume that a muscle 'is ideally designed to meet that one alone under other conditions other demands also must be met" In the chapter on comparative physiology of muscle, C F A Pantin points out that the physico-chemical basis of movement is very often substantially the same "This restricted pattern of variation is not simply of evolutionary origin it depends also upon the peculiarly limited chemical materials available for living systems, and the limitations set by the properties of matter"

A F Huxley and H E Huxley write elegantly on the ultrastructure of muscle and on the function and composition of the familiar striations K. Bailey and S V Perry give lucid accounts of present ideas on contraction and relaxation and on the part played by the various muscle proteins and phosphates B Katz is, as usual, clarity itself in discussing the rôle of the cell *membrane in muscular activity*, and the account of the nervous gradation of muscular contraction by P H Hammond, P A Merton and G G Sutton is very well done A V Hill's article on the thermodynamics of muscle makes it easy to understand the kind of information which can be obtained by physical measurements of this type Of great interest too are the accounts of energy production in muscle, its comparative physiology, activity during locomotion, problems of fatigue, and changes after death The article on muscular effort is written by R G Bannister, whose knowledge is both subjective and objective To anyone whose interest in physiology is largely based on a desire to understand human physiology the chapter on familial periodic paralysis by B McArdle will be of particular interest, since it provides an admirable summary of possible causes underlying one variety of this disease, whose nature can only be rightly understood, and therefore rightly treated, if the normal physiology and biochemistry of muscle is appreciated

[2] *Brit med Bull* 1956 12 no 3 Price 15*s*

Into a brief preface Sir Rudolph Peters packs some history and much wisdom He knows how the clinician may be exasperated because the scientist works in apparent remoteness from the obvious practical situation, but he points out the importance of studying basic problems as a means of getting practical results as well as illumination of knowledge.

University of Cambridge

On Dec 15 the following degrees were conferred

M D—J H Gough J W T Redfearn
M B , B Chir—A O Peters

Dr L B Cole has been appointed deputy for the regius professor of physic, and Dr F G J Hayhoe deputy head of the department of medicine

University of London

Dr Eric Neil, reader in physiology at Middlesex Hospital Medical School, has been appointed to the John Astor chair of physiology at the school

Dr Neil graduated B SC with first class honours in physiology in the University of Leeds in 1939 and M B in 1942 For the next three years he served as demonstrator in physiology at the Leeds Medical School In 1945 he was appointed temporary lecturer and a year later lecturer in physiology at the school From 1949 to 1951 he spent some time each year in Stockholm working at the royal veterinary college under Professor Zotterman In 1950 Dr Neil was appointed senior lecturer in physiology at Middlesex Hospital Medical School, and in 1952 he was appointed to the readership in physiology His published work includes a study of methods of artificial respiration and papers on chemoceptors and the circulation

The title of reader in pharmacology has been conferred on Dr J A Nissim in respect of his post at Guy's Hospital Medical School

University of Manchester

At recent examinations the following were successful

M B , Ch B—K S Ansell, P J Barber Kenneth Bass Arthur Booth, A T Cartmell B W Chant, J D Corcoran Joan M Curtis I W Dade, Moira P Dillon, Cynthia M Dixon, A M Easty, W O Goldthorp, Brian Graham, E A G Hamilton, G A Harris D D Hilton, Irene Holbrook Keith Horsfield, H C Jennings T A Lambros Elizabeth J Larrad J R Ledwich Brenda J Lovejoy, K A Mackenzie, Peter McKelvie, Elizabeth M B McKenzie, Edith M Meyer Peter Morris, Harold Nickson J P O'Loughlin Amos Pacovsky, H W Proctor A R Robertson D T Robinson J H Scotson, Barbara S Seymour, D B Shaw N M Shaw S A Silver, J J Slater Eleanor M Stocks A G Tetlow M H Vause, Desmond Walker, W B Waring, R D Wood, A B Wootliff

Royal Society

Prof G L Brown has been appointed a vice president of this society for the coming year

Fulbright Travel Grants

The United States Educational Commission in the United Kingdom have announced that these grants are available to citizens of the United Kingdom and Colonies to go to America for an academic or educational purpose, such as study, research, or lecturing Further particulars may be had from the commission, 71 South Audley Street London, W 1

United Hospitals Catholic Society

This society has arranged a course of lectures on medical ethics The lectures will be held at the Chaplaincy, 13 Devonshire Place London W 1, on alternate Mondays at 6 15 P M The Rev John McDonald will give the first lecture on Jan 7, and other speakers will be Dr F Harwood Stevenson Mr Ambrose King Mr John Ryan Mr Leslie Williams Mr J A O Sullivan, and Dr Charles Burns

Release of Prednisone and Prednisolone

From Feb 1 prednisone and prednisolone will be supplied on prescription

World Health Organisation

Dr P M Kaul, formerly director of W H O 's division of external relations and technical assistance, has been appointed assistant director general in charge of the department of advisory services

Awards for Medical Films

The *Presse médicale* is again offering a prize (fr 100,000) and other awards for unpublished amateur films (16 mm) Films must reach the secretariat of the journal, 120, boulevard *Saint Germain, Paris VI*, by Feb 28

Research Board for the Correlation of Medical Science and Physical Education

The William Hyde award (£300) for 1956 has been made to Squadron-leader C B Wynn Parry for his work on physical medicine in the Royal Air Force This is the last award, for the board, having completed its research investigations is closing, and is transferring its remaining funds to the Physical Education Association of Great Britain and Northern Ireland

Reciprocal Agreements on Social Security with the Federal German Republic

Reciprocal agreements on social security have been signed by Ministers of the United Kingdom and the Federal German Republic One agreement covers unemployment insurance and assistance, and the other covers all other national insurance and *industrial injuries* benefits A *protocol* on health services entitles people who go from the United Kingdom to Germany for employment, and certain groups of national insurance beneficiaries, to take advantage of the German health services in return for the facilities available to Germans in this country The agreements will not come into effect until they have been ratified

Prof W W Mushin is to address the New York State Medical Society at its sesquicentennial celebrations in February, and in March he will be a visiting professor of surgery (anesthetics) at the University of California medical centre in Los Angeles

PORTACAVAL ANASTOMOSIS

R Milnes Walker
M S Lond , F R C S
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL

With illustrations on plate

In a previous communication (Walker 1952) the opinion was expressed that venous shunts had a definite place in the treatment of portal hypertension, and that an end-to-side portacaval anastomosis was the most satisfactory if it could be done As a result of further experience, definite indications for the operation were laid down (Walker 1954), and since that time there has been no reason to modify these indications or the type of operation then advocated Now that more than 50 patients in this department have survived the operation and some of them have been followed for five years or more, the time seems appropriate to review the results

Indications for Operation

The indications adopted may be set down precisely Hæmorrhage from œsophageal or gastric varices due to intrahepatic venous obstruction, and the risk of such hæmorrhage when large varices are present, are the only indications Certain contra-indications may exist in patients who have had such hæmorrhage For example, the liver function may be too severely impaired, the portal vein may be thrombosed or "cavernomatous" and therefore unsuitable for such an anastomosis, or in elderly patients the risk of subsequent thrombosis may be considered too great

These indications and contra-indications can now be reviewed in greater detail That the hæmorrhage comes from varices may be suspected by finding that the patient has an enlarged spleen or ascites, but their presence is usually confirmed radiologically or, on occasions, by œsophagoscopy If varices are present, it may be presumed that they are the source of the bleeding, but in some cases a peptic ulcer is present also, and then it may be very difficult to decide which is the cause

That the venous obstruction is intrahepatic is not so easy to demonstrate, but previous jaundice, ascites, and impaired liver function suggest intrahepatic disease Extrahepatic obstruction, however, may be present at the same time, from thrombosis in the portal venous system It is here that transsplenic portal venography plays an important part in the investigation and selection of these patients because it will indicate the site of the obstruction and show whether the portal vein is sufficiently healthy for the operation (fig 1) This investigation was made on all the patients operated on since 1952 except one who had had his spleen removed The state of the portal vein was indicated so clearly that, in every patient but one in whom the operation was planned, it was possible to complete the anastomosis

The exception was a woman, aged 66, who in 1948 had a cholecystectomy and three years later further exploration of her common bile duct In June, 1953, she had her first hæmatemesis, and between December, 1953, and March, 1954, she bled at short intervals A period of a few days without bleeding was thought to be possibly the last chance for operation, which was attempted in spite of the fact that she bled again just before the anæsthesia was induced Very dense vascular adhesions, the result of her previous operations, led to the abandonment of the operation, and she died after further hæmatemesis next day At her age, and because the bleeding recurred just before operation, a change of plan and a direct operation on the œsophagus would have been a wiser course

Before the use of routine transsplenic venography to localise the venous obstruction 4 patients were explored with a view to a portacaval anastomosis but the operation was impossible because they were found to have complete thrombosis of the portal vein—in 3 secondary to cirrhosis of the liver, and in the 4th due to a primary extrahepatic obstruction In 1 patient, owing to mural thrombi in its lumen, the portal vein was so adherent that it could not be approximated to the inferior vena cava , so a side-to-side anastomosis was made with an autogenous vein-graft to bridge the gap

Without a venogram it is sometimes impossible to distinguish whether the obstruction is intrahepatic or extrahepatic A few patients seemed eminently suitable for a portacaval anastomosis until this radiological investigation showed that they had extrahepatic obstruction and the portal vein was unsuitable for anastomosis (fig 2) On these patients an alternative operation had to be done

A portacaval anastomosis was not advised if there was evidence of severe liver disease, indicated by jaundice, gross ascites, or abnormal liver-function tests Moderate ascites, however, is not a contra-indication The liver-function test to which most weight was attached is the serum-albumin level, and no end-to side portacaval anastomosis in this series was done on a patient whose serum-albumin level was below 3 g per 100 ml at the time of operation Most patients had normal serum-alkaline phosphatase levels, but in 10 the level was above 20 King-Armstrong units, and in 3 it was exceptionally high, though there was no evidence of obstructive jaundice 1 patient, with a level of 43 units, had schistosomiasis of the liver , another, with 51 units, developed postoperative jaundice, which persisted for three months, but still no cause of obstruction was evident , and the 3rd, whose phosphatase level was 62 units, had a stone in the common bile duct, though she had never had jaundice A high serum-alkaline-phosphatase level is therefore no contra-indication to the operation

Flocculation tests were abnormal in about half the cases , this finding is no contra-indication to the operation, but the liver deficiency which they indicate may predispose to neurological complications afterwards Bromsulphalein excretion tests were done on only a few of the patients in the group

Patients

The present series comprises 56 patients who had end to side portacaval anastomoses, and 53 of them survived the operation and left hospital The cause of the fibrosis in the liver is only definitely known in a minority 2 patients had hæmochromatosis , 1 had Wilson's disease , and 1 had schistosomiasis A few gave a history of attacks of acute or subacute hepatitis, but only 2 gave a definite story of alcoholism (1 drank 5 pints of cider and 4 pints of beer daily for twenty years, and the other 7 or 8 bottles of stout daily from the age of 16 to 45) Many were seen within a few months of their first hæmatemesis, but others had had repeated hæmorrhages for periods up to eleven years 3 gave no history of bleeding but complained of either lassitude (2 cases) or diarrhœa (1 case) and were found to have splenomegaly and large varices

2 patients had already had their spleens removed, but the bleeding had recurred with renewed virulence Another had had a splenorenal anastomosis, which had become occluded The ages at the time of the first bleeding ranged from 5 to 53 years and at operation from 7 to 57 years

Operation

In every case the exposure was by a right thoraco abdominal approach through the bed of a rib, usually the ninth, the incision extending across the costal margin The diaphragm was split to allow upward displacement of the liver, the portal vein was divided as high as possible, and its lower end was anastomosed by continuous everting mattress sutures to the side of the inferior vena cava At 48 operations, before the anastomosis was made, the portal pressure was measured either in the portal vein itself or in one of its tributaries, and ranged from 160 mm H_2O to 570 mm H_2O (average 330 mm H_2O) In 8 cases some thrombosis was found in the portal vein, usually an old adherent mural clot, but in 4 cases portions of clot were removed to enlarge the lumen The presence of thrombosis in the portal circulation adds to the severity of the disease, because 2 of these 8 patients died Splenectomy seems to add to the risk of thrombosis, because both patients who had had their spleens removed previously had mural thrombi, and these 2 are the only survivors who have had any serious bleeding since the operation

In many cases, when the anastomosis is completed the turbulence set up by the inflow of portal blood can be seen through the thin wall of the inferior vena cava Anticoagulants were not used as a routine postoperatively Postoperative venography was done on 6 patients only, but all these showed a free flow into the inferior vena cava (fig 3)

Results

All the patients were followed up either by attendance or by correspondence for periods ranging up to five and three quarter years after their operation 3 patients died while still in hospital

(1) A woman, aged 38, had a severe hæmatemesis five months before her operation, previously she had had a subarachnoid hæmorrhage and petechiæ on her legs Her albumin/globulin ratio was 1 1 3 and bromsulphalein retention 22% after one hour On the day after operation she became drowsy and comatose, a tracheotomy was done to ease her breathing, and her state of consciousness varied, but she died on the thirtieth postoperative day At necropsy the anastomosis was patent

(2) A boy had bronchiectasis following an empyema at the age of 14 Hæmatemesis first occurred in 1944 at the age of 23, and during the next eight years he received more than 50 pints of blood, transfusions being necessary on six occasions during the year before his operation His portal vein contained adherent clot, which was removed with difficulty Two days after the operation he became unconscious but recovered fully, only to lapse into unconsciousness again on the twelfth postoperative day, after resuture of his wound, which had partly given way during a bout of coughing He died two days later, and a necropsy was not permitted

(3) A man, aged 45, had had numerous hæmatemeses during the previous two and a half years Two laparotomies had been done, at the first some veins had been ligatured, and at the second an attempt had been made to ligature the hepatic artery Though a lumen was present, his portal vein contained much organised thrombus, and, when the clamp was released, there was only a slow stream of blood When the liver was incised for biopsy, arterial blood spurted out, showing that the hepatic artery was patent This patient became drowsy on the fifth postoperative day and died two days later Necropsy showed extensive thrombosis in the portal system, the anastomosis being almost occluded and the splenic vein entirely blocked Fresh bleeding had taken place from a ruptured œsophageal varix It is clear that this patient was unsuitable for the operation, because the occluded splenic vein would prevent decompression of this part of the portal circulation, in the venograms a large collateral had been mistaken for the splenic vein

5 patients who left hospital have died since 1 of these died of general peritonitis due to a ruptured pyosalpinx four months after her operation, at necropsy the anastomosis was patent The other 4 died as a result of their liver disease

(1) A man had a side to side splenorenal anastomosis without removal of the spleen in 1949, after further bleeding a direct operation on his varices was done in 1951, in spite of this he bled again and his portacaval anastomosis was done in 1951 He died after further hæmorrhage eight months later At necropsy the splenorenal anastomosis was closed, but the portacaval opening was patent without any thrombus The explanation of his death may be that, the splenic vein being thrombosed, the anastomosis did not relieve the hypertension in the spleen

(2) A woman had three severe hæmorrhages in March 1954, for which she was transfused with 12 pints of blood Her other complaints were pain in the right upper quadrant of her abdomen, breathlessness, and a little swelling of her leg Her liver was hard, and radiography showed much calcification in its capsule She also had severe leucopenia (600 white cell per c mm) and thrombocytopenia A portacaval anastomosis was made in May, 1954 She was well for some months but increasing hæmolytic anæmia called for further blood transfusions and, because this was thought to be due to hypersplenism, her spleen was removed in August, 1955 Shortly before this operation she had an episode of hepatic coma lasting three days After the splenectomy the anæmia improved, but she had further episodes of drowsiness, and died in coma in February, 1956 Histological evidence showed that she had hæmochromatosis

(3) and (4) 2 patients died of liver failure thirty three and twenty eight months after operation without any recurrence of hæmorrhage

Apart from the cases referred to already, only 2 patients had any recurrence of hæmorrhage

(1) A man was diagnosed as having anæmia while in the Royal Air Force in 1943 Two years later, after numerous attacks of melæna, his spleen was removed Eight months after this he had the first of a series of hæmatemeses, and a portacaval anastomosis was made in 1951, at that time his portal venous pressure was 300 mm H_2O Slight melæna occurred in 1952, and a year later he had a severe hæmorrhage A direct operation on his varices was undertaken, and in the three years since then he has had two slight hæmorrhages, otherwise he remains well

(2) A man had his first hæmorrhage in 1942 at the age of 19 In 1944 his spleen was removed, but repeated hæmorrhages continued, and he required many blood transfusions In January, 1953, the portacaval anastomosis was made, and at that time a thrombus was adherent to the anterior wall of the portal vein His portal venous pressure was only 160 mm H_2O Only eight weeks after this operation bleeding recurred and, after a severe attack in the following September, a direct operation on his varices was done Since then bleeding has not recurred, œsophagoscopy shows hardly any varices, and he works as a radio engineer

The reason for the recurrence of bleeding in these 2 patients is not clear, but the only 3 patients in this series who have had any significant bleeding after leaving hospital had all had either a splenectomy or a failed splenorenal anastomosis No other patient in the series had had the spleen removed, and no patient who had a portal venous system which had not previously been interfered with has had any serious bleeding since the operation

Complications of Operation

Complications of the operation were, with one exception, rare slight wound infection in a few cases, a pneumothorax once, and transient jaundice The serious complication is the neuropathy associated with portal systemic shunts, whether natural or produced by the surgeon (Sherlock et al 1954) It has already been noted that coma was the cause of death in the 3 patients who died in hospital 9 other patients had episodes of encephalopathy In 1 the only manifestation was excessive salivation, which persisted for two years after his operation but has now subsided 4 had episodes of coma, 1 has already been described (see above), in another the attacks persisted for four months after her operation, and 1 patient had a single attack, five weeks after operation, from which she made a rapid recovery In the 4th of these patients the coma followed partial gastrectomy for peptic ulcer nearly two years after his venous shunt 1 patient was so queer on returning home that her doctor sent her into a mental hospital, but when the nature of her condition was recognised and appropriately treated, she made a complete recovery

3 more had transient mental disorientation, usually soon after returning home, and the patient who died of a ruptured pyosalpinx was definitely slow mentally for the first six postoperative weeks One patient has had periods of depression and mental distress during the three years since her operation, but biochemical tests suggest that she does not fall into this group of hepatic neuropathies

It seems that the danger of these complications is greatest soon after patients return home, and the episode may be precipitated by eating a large protein meal Usually there is a quick response when the patient is put on a protein-free diet, and in most cases a steady return to normal diet can be permitted Patients with defective liver function are much more liable to these complications, but 5 of the 13 who developed neurological symptoms had normal liver-function tests

Two symptoms were noted during the follow-up (1) occasional epistaxis and œdema of the legs occurred in 2 patients and may be the result of the operation or may be caused by the disease of the liver, and (2) 1 patient has ulcerative colitis four years after her operation—an example of the well-recognised association between these two diseases

In the great majority of patients there has been no evidence of deterioration of the function of the liver during the years that they have been followed up, the cirrhosis appears to be static Liver-function tests were made on practically all of them and usually showed little change from the preoperative values Some of the patients had leucopenia and thrombocytopenia before the operation, and this tended to improve slowly, in only 1 case (see above) was it considered necessary to remove the spleen because of continued hæmolysis, thought to be due to hypersplenism The reduction in size of the spleen is most striking within the first day the apex recedes, but after this further reduction is slow and may continue for years, until often it eventually ceases to be palpable Only a few patients had recognisable ascites before operation, and in no case was it necessary to do paracentesis afterwards

Most of the patients are leading normal lives, in the few who are incapacitated, so that they cannot work, the cause is to be found in the associated disease of the liver

Conclusions

As a means of preventing hæmorrhage from œsophageal varices in patients in whom the operation is feasible an end-to side portacaval anastomosis is most effective By careful selection of patients the operative risk is small (3 deaths in 56 cases), and the results are most satisfactory unless some disease is causing progressive deterioration of the function of the liver The most serious drawback of the operation is the neuropathy which may result from a large portal systemic shunt Symptoms, usually transient, develop in about 20% of cases but are rare in those whose liver function is normal

In a follow up extending to five and three-quarter years 2 patients who had previously undergone splenectomy both had a recurrence of hæmorrhage but after an operation on their varices they returned to their occupations There was no recurrence of hæmorrhage from varices in the 50 survivors who had not had a previous operation involving the portal venous system but 4 died subsequently 1 of hæmochromatosis 2 of their cirrhosis, and 1 of unrelated disease Of the 46 remaining 35 have no symptoms and are leading perfectly normal lives and 7 have been operated on too recently to be back at their occupations

This series of cases shows that an efficient end-to side portacaval anastomosis will greatly reduce the risk of further hæmorrhage in cases of portal hypertension due to intrahepatic disease

My thanks are due to so many people who have coöperated in the management of these patients that I cannot mention them all, so I refer only to the sisters, nurses, and house-surgeons who have given them such great care and the doctors—specialists and general practitioners—who have entrusted me with the care of their patients and assisted in following them up Part of the cost of the recording manometer used was defrayed by a grant from the Medical Research Council

With illustrations on plate

From the atypical pneumonias of infancy, European observers have separated a specific clinical and pathological entity which they called interstitial plasma-cell pneumonia This disease, as seen on the Continent, affects chiefly premature and immature weakly infants, aged 2–5 months, many of whom have been in institutions for some time Although it is sometimes preceded by diarrhœa or an acute infection of the upper respiratory tract, its onset is generally insidious, mild ill health being followed by respiratory upset with tachypnœa, dyspnœa, and cyanosis, these increase gradually or rapidly, and death, if it happens, occurs with extreme asphyxia Cough is trivial The objective findings are curiously slight, thus there is little or no fever, and clinical examination of the chest may reveal nothing abnormal In striking contrast with this is the radiological picture which shows obvious mottled opacity, sometimes even before respiratory symptoms have appeared The illness lasts 1–6 weeks, occasionally longer The variation of the reports on mortality, from 15 to 100%, no doubt reflects the difficulty of clinical diagnosis Histopathological diagnosis has in recent years become more certain, the two main features being an intra alveolar "exudate" of unusual foamy or granular appearance and thickening of alveolar septa by an infiltrate of mononuclear cells often rich in plasma-cells The ætiology is still very much a matter of debate, and the term "pneumocystis" pneumonia has come into use on the basis of one of the ætiological hypotheses (see below)

Most of the published cases have been in Switzerland, Czechoslovakia, Germany, and Finland, where pneumocystis pneumonia is considered a relatively common disease, in these countries small epidemics have also occurred, of five to twenty cases, usually in hospital wards The disease next appeared, or was recognised, in Italy, Hungary, Sweden, Denmark France, and Holland, but thus far usually as sporadic cases Its first mention in America was in 1955 (Lunseth et al 1955), and a detailed study of a case followed in 1956 (Dauzier et al 1956) Five cases have now been described in Canada (Donohue 1956, Gagne and Hould 1956) The first case to be published in England was seen by Baar (1955), who later in that year recognised from the photomicrographs (Hutchison 1955b) that a case of congenital agammaglobulinæmia in Glasgow reported by Hutchison (1955a) had the characteristic pulmonary changes

During the past year two children have died in Dundee with a clinical and pathological picture which we believe conforms with this curious disease, although both children were older than is usual in the Continental cases

The Illness

FIRST CASE

A male infant, aged 9 months was admitted to Dundee Royal Infirmary on July 23, 1955, because of recurrent vomiting, failure to gain weight, a cough for 3 months, and a discharge from the right ear for 1 month

He had been born by spontaneous breech delivery at term, weighing $6^3/_4$ lb Fed on National dried milk, he had always had a poor appetite and gained weight slowly, and latterly he had seemed to be wasting Vomiting started at the age of 7 weeks and came on thereafter for periods of about 2 weeks, with free intervals of the same duration, it was sometimes forceful and happened during or after feeding When 3 months old he had a frank convulsion, and in the succeeding 3 months he had attacks in which his limbs stiffened and his eyes rolled up At 6 months he developed a cough, which persisted without remission until he was admitted to hospital Both parents, who are not related, and four older children are all in normally good health, with normal chest radiographs

On admission he was poorly nourished, looked toxic, and weighed 14 lb 3 oz He was apyrexial but moderately dyspnœic, with respirations 40–50 per min Muscle tone was poor The gums were red and inflamed, and he had a few shallow white ulcers on his palate The alæ nasi moved with respiration, and there was slight intercostal indrawing Percussion note and air entry were normal throughout the chest, but occasional crepitations were heard at both bases Chest radiography showed diffuse fluffy mottling throughout both lung fields (fig 1)

Course in Hospital

A diagnosis of bronchopneumonia was made and treatment with penicillin and sulphamezathine was begun

There was little improvement during the next week, cough being persistent, vomiting still fairly frequent, and the X-ray picture unchanged Streptomycin was substituted, and there was some improvement for the next 12 days, but radiography showed increased mottling (fig 2) On Aug 12 the baby's condition changed rapidly, with dyspnœa, tachypnœa, and cyanosis His pulse and respiration rates rose, and he died on Aug 18

Laboratory Investigations

The white cell count on admission was 31,000 per c mm, with a preponderance of neutrophils, hæmoglobin 12 g per 100 ml, and erythrocyte sedimentation rate (E S R) 10 mm in 1 hour (Wintrobe) Nothing abnormal was found in the urine, and lumbar puncture revealed normal cerebrospinal fluid The Mantoux reaction was negative (1 2000), and no tubercle bacilli were found in gastric washings Stool examinations for tryptic activity were positive, and repeated culture of the stools did not produce any pathogens

The white cell count settled around 12,000 per c mm (differential count normal), and the E S R remained at 10 mm in 1 hour *Staphylococcus aureus* was grown on one occasion from throat swabs, but fungi were not isolated

The most striking findings in this infant were the negative physical signs in the chest, in contrast to the increasing dyspnœa and cyanosis, and the gross radiological changes throughout the illness

SECOND CASE

A male infant, aged 11 months, was admitted to Arbroath Infirmary on Jan 18, 1956, because of cough which had persisted for 3 months

He was born at term and weighed 9 lb 7 oz Everything seemed normal then, and he was breast fed for 9 months His only illness was infantile eczema, because of this he was not vaccinated or otherwise immunised Both parents are healthy and have normal chest X rays There had been two other children, both male The first died in 1952, aged 4 months, with *Shigella sonnei* dysentery, and the second died in 1954, aged 5 months, with gastro enteritis associated with *Escherichia coli neopolitanum 055* and pneumonia No necropsies were performed

When 8 months old he developed a running nose, and the discharge soon became yellow and purulent Cough appeared and persisted 6 weeks before admission he had an attack of wheezing, shortness of breath, and pyrexia This was treated with penicillin and chloramphenicol orally with considerable improvement but the cough persisted 3 days before admission he developed thrush in his mouth and became restless and feverish with rapid breathing

On admission he was an ill child, irritable and poorly nourished There was slight dehydration and hypotonia He had fever (103°F) with respirations 50 per min, but there was no dyspnœa or cyanosis The percussion note was impaired over the right chest anteriorly, and pneumonia of the right middle lobe was demonstrated radiologically (Dr T Sprunt)

Course in Hospital

Penicillin and sulphadimidine were given His temperature fell to normal within 48 hours, and there was rapid resolution of physical and radiological signs in the chest His general condition improved, but his cough persisted and after 7 days radiography showed diffuse fluffy mottling throughout both lung fields, most marked towards the hilum with relatively clear peripheral fields During the next 2 weeks these changes increased despite the absence of physical signs (fig 3), and pneumocystis pneumonia was tentatively diagnosed

He was transferred on Feb 11 to Dundee Royal Infirmary, where treatment was continued with courses of penicillin sulphamezathine, streptomycin, erythromycin, and tetracycline, with no obvious benefit His clinical condition remained unchanged without causing undue anxiety, but radiography showed progressive pulmonary changes (fig 4) Hypogammaglobulinæmia was first sought and found on Feb 21 2 days later his condition changed rapidly, and he became dyspnœic, with respirations up to 90 per min and a pale greyish cyanosis, relieved only by oxygen

Gamma globulin was given intramuscularly in doses of 1 g to a total of 6 g during the next 12 days with no apparent effect

Because of the pattern of the illness, with tachypnœa dyspnœa, cyanosis, and negative physical signs, but gross radiological changes and failure of response to antibiotics we felt more confident of the diagnosis of pneumocystis pneumonia He was given pamaquin 2 mg five times daily for 6 days, followed by mepacrine 25 mg twice daily for 6 days and for 2 days by 'Infant Acetylarsen' 1 ml daily (Dvorak and Jirovec 1953) Chloramphenicol was substituted for other antibiotics (Eberle et al 1955)

From the time of this dramatic change in his condition he steadily deteriorated and was cyanosed whenever out of oxygen On Feb 26 he developed transient clubbing of the fingers and toes for 4–5 days

The temperature, white cell count, and E S R remained normal The picture was now one of steadily increasing asphyxia (fig 5) The infant became gradually thinner, more fretful, and apprehensive, and on March 18 he developed subcutaneous emphysema over his neck and upper chest, with bilateral pneumothorax He died next day

Laboratory Investigations

On admission to Dundee Royal Infirmary his white cell count was 10,000 per c mm (differential count normal) hæmoglobin 14 8 g per 100 ml, and E S R 4 mm in 1 hour (Wintrobe) His urine was normal on several occasions, and proteinuria was never found

Extensive investigation of his blood chemistry showed no abnormality In view of the association reported between interstitial plasma cell pneumonia and hypercalcæmia (Hallman et al 1954) it may be noted that the plasma calcium level

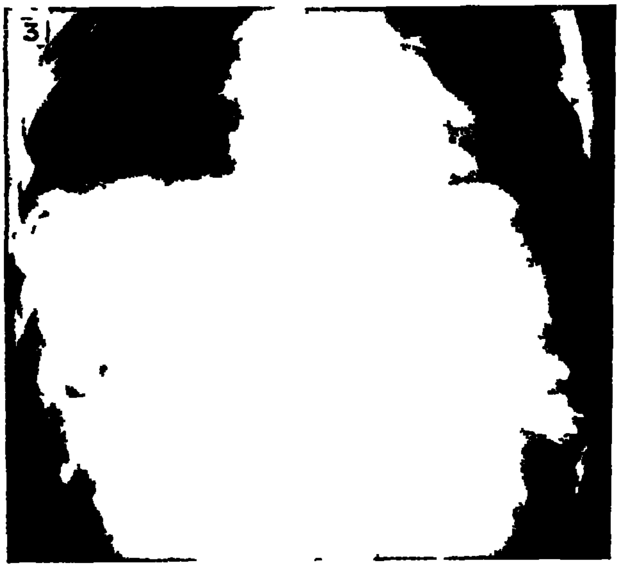
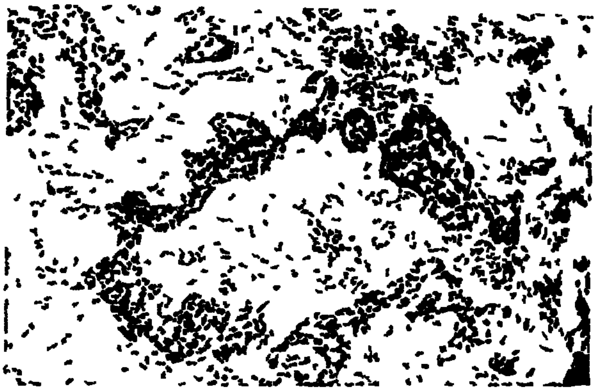
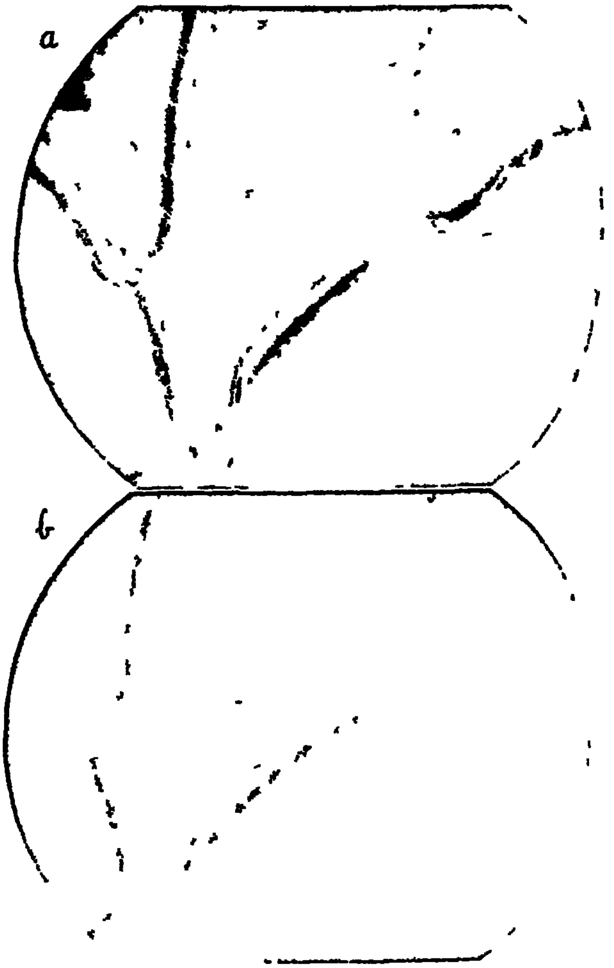
PROF MILNES WALKER PORTACAVAL ANASTOMOSIS



PROF GILLMAN AND OTHERS ALLOXAN



DR SNOW SLUDGING OF BLOOD



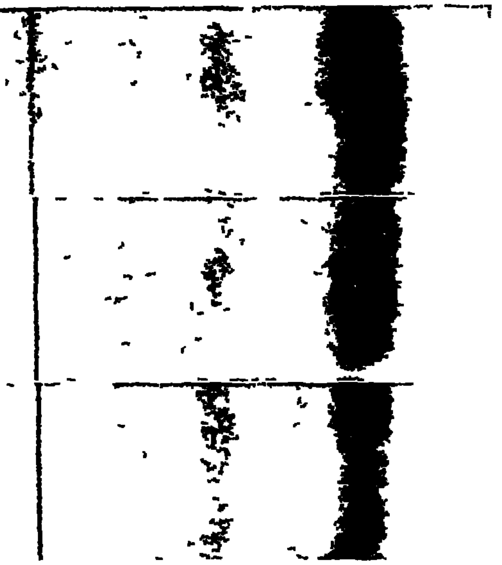


Fig 6—Top register "normal" infant aged 12 months, middle register case 2 showing absence of gamma globulin (Feb 21, 1956), bottom register case 2, after intramuscular gamma globulin 6 g showing no obvious change (March 6, 1956)

was only 9 8 mg per 100 ml and the plasma phosphorus level 4 2 mg per 100 ml on two occasions

Pancreatic trypsin was demonstrated in the fæces on several occasions The white cell count varied from 7000 to 10,000 per c mm, and differential counts showed a slight increase of polymorphonuclear cells The hæmoglobin was always more than 14 g per 100 ml

Staph aureus, resistant to all antibiotics tried, was twice isolated from the nose During the last week *Esch coli neapolitanum 0119* was isolated from the stools, but there was no diarrhœa

Serum proteins were low from the time of admission The total was never more than 4 9 g per 100 ml, the albumin varying from 3 2 to 3 4 g and the globulin from 1 5 to 1 7 g Paper electrophoresis (fig 6) on Feb 21 showed an absence of gamma globulin, confirmed on following days, and chemical fractionation (Wolfson et al 1948) revealed levels of about 75 mg per 100 ml (Miss R Haslock) There was a slight increase of alpha 1 and alpha 2 globulin The normal level of gamma globulin at the age of 12 months is 450–700 mg per 100 ml (Moore et al 1949, Corbiel et al 1954) and rises to the adult level of 1000–1200 mg in later childhood

No changes were noted during the remainder of the illness after the administration of gamma globulin in large doses, apart from an increase in alpha 1 globulin

Electrophoresis and chemical fractionation of both parents' serum gave normal findings

The blood group was O Rh-positive, and no iso agglutinins anti-A or anti-B could be demonstrated at 4°C, room temperature, and 37°C by the methods recommended by Dunsford (1953) (Dr F S Graham)

Comment on Radiographs (Dr C Pickard)

A widely disseminated granular lesion of the lung fields but detailed examination shows the opacities to have a fluffy irregular outline, unlike the discrete characteristics of miliary lesions There is no evidence of hilar glandular enlargement The pattern progresses to more widespread and confluent fluffy opacities The general impression is of a disseminated alveolar lesion becoming lobular and ultimately widespread

Post-mortem Findings

FIRST CASE (Dr H G Morgan)

Examination 16 hours after death A slightly dehydrated infant, the only significant gross findings being in the lungs There was no pleural reaction or fluid, and both lungs showed an identical appearance, being finely nodular throughout all lobes, with no predilection for any site The pattern suggested bronchopneumonia, but even the smallest of the visible bronchi appeared unaffected Most of the nodular areas were 1–3 mm in diameter, whitish, and firm, and the intervening lung was firmer and drier than normal, with small areas of emphysema The larger bronchi contained a little mucus but no pus or aspirated material The paratracheal and bronchopulmonary lymph-nodes were not enlarged

Culture of lung tissue produced a growth of pneumococci and *Candida albicans*

Other organs showed no abnormality, and there was no lymphadenopathy or splenomegaly The middle ears contained no pus

Microscopy

In the nodular areas described in the lungs there is a diffuse interstitial infiltration of mononuclear cells, including plasma-cells, with only occasional polymorphs The alveoli and alveolar ducts are filled with a weakly eosinophilic exudate of granular, foamy, or honeycomb appearance The sponge-work is brilliantly fuchsinophil with the periodic acid Schiff reaction, but is completely negative for fibrin, mucin, and glycogen (fig 7) With the Schiff method, Giemsa's stain, or toluidine blue, many of the clear spaces, particularly at the periphery of the honeycomb, are seen to contain one or more free lying tiny granular bodies In most places the intra alveolar exudate is quite acellular, but there is frequently a prominent alveolar lining with cuboidal cells Desquamated cells occasionally seen in the exudate sometimes contain finely granular fat or Schiff-positive granules In other places the exudate appears to have undergone necrosis, and the peripheral cells then are of foreign-body giant cell type In these small granulomatous foci the necrotic exudate has taken up calcium, but this is rare and not likely to be the explanation of the severe and widespread radiological change Between the nodular areas of consolidation the lung shows a *moderate* diffuse infiltration of the alveolar septa by a mononuclear cell infiltrate, associated often with areas of emphysema There is no evidence of cytomegalic or other inclusion bodies

Sections made from other viscera, including lymph nodes, spleen, and bone marrow, are all normal, and there is no evidence of inclusion disease in pancreas, kidney, or salivary glands The lymph nodes from numerous sites are small, containing only a few primary, and no secondary, follicles Smears and sections from the nodes, spleen, and bone marrow show only a very occasional plasma cell In the kidneys an occasional tiny focus of calcium deposition is seen in collecting tubules, sometimes associated with a slight granulomatous reaction

SECOND CASE

Examination 2 hours after death showed a thin wasted cyanotic infant, with subcutaneous emphysema over the chest

To slow the stream sufficiently for photography, relatively firm pressure was applied to the eye by the patient himself hence the appearance of sludging in the arteries as well as the veins When the photograph was taken, the E S R was 50 mm in one hour, and the serum globulin level 5 g per 100 ml A diagnosis of Hodgkin's disease was established three months later

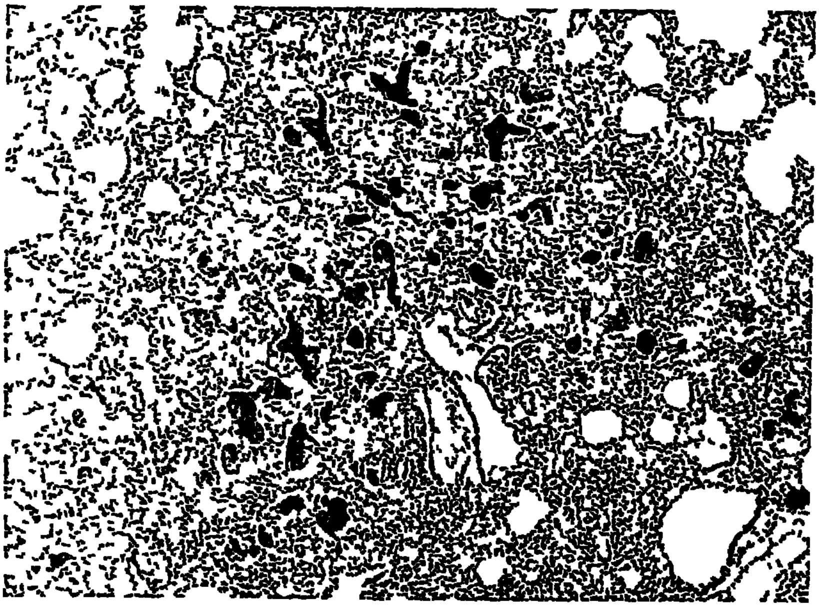

Fig 7—Case 1 lung showing "exudate" as dark masses in alveoli and as grey granular material in bronchiole Note thickening of alveolar septa by cellular infiltrate (Periodic acid Schiff × 60)

posteriorly and reaching up to the root of the neck Gross changes were confined to the thorax There was bilateral pneumothorax, but the lungs were bulky and retained their shape The pleural surfaces were normal apart from occasional small subpleural hæmorrhages and interstitial emphysema, and there were collections of air at the hila, extending behind the parietal pleura to reach the neck

The lungs were pinkish-white and diffusely firm, with a rubbery consistence, and all the lobes were equally affected Only the margins obviously contained air, and here occasional subpleural spaces up to 0 5 cm in diameter were seen Throughout both lungs the lobular pattern was accentuated, and, with the colour and consistence, resembled pancreas or thymus—suggesting the term "pancreatisation" The bronchi contained a little viscid mucus, their cut surface was rather dry, and only a little serous fluid was obtained on scraping

The paratracheal and bronchopulmonary lymph nodes were small There was a mild thrush œsophagitis, and the only other striking feature was the striking deficiency of lymphoid tissue throughout the body, though the spleen was of normal weight No abnormality was seen in other organs

Microscopy

The changes in the lungs are essentially the same as in case 1, but more widespread and uniform There are no areas of necrosis and granulomatous change, and no plasma cells are seen in the interstitial infiltrate (figs 8 and 9) The lungs therefore resemble more closely the Continental descriptions except for the absence of plasma cells

There is no evidence of inclusion disease of parasites in the other viscera The lymph nodes, spleen and bone marrow are similar to those in case 1, but no plasma cells can be seen

Sections and material were sent to Professor Hamperl (Bonn), Professor Vanek (Prague), Dr Le Tan Vinh (Paris), and Dr E K Ahvenainen (Helsinki) all agreed that this was the disease they had described and were willing to accept the absence of plasma cells as in some way associated with hypogammaglobulinæmia Using the modified del Rio Hortega method of Le Tan Vinh (1954) we have succeeded in showing in sections the cysts described by him and shown by Hamperl (1956b) by phase contrast microscopy in smears (fig 10) Dr Le Tan Vinh was kind enough to stain and study our material and said that he regarded the cysts as pathognomonic

We hope to describe the microscopy of this disease more fully elsewhere, but meanwhile it may be said that the interstitial changes are moderate, plasma cells are not the predominent type in either case, and the pathognomonic feature in both cases is the intra-alveolar spongework (see below) It is generally agreed that the responsible organisms are best seen in lung imprints In our hands Giemsa's stain gave the best results, and fig 11 shows the appearance in smears made at necropsy The honeycomb structure apparent in the sections is again seen, but in addition there are more obvious cyst like structures, 5–9 µ in diameter, containing small round bodies which are uniformly basophilic Routine cultures and injection of lung extracts into guinea pigs and rabbits did not produce pyogenic bacteria or fungi

Discussion

Clinical Definition

The clinical definition of this disease is likely to become sharper with the advent of the new histopathological criteria The question, however, will probably remain whether all the many cases described in the past as interstitial plasma cell pneumonia were the very specific anatomical entity which at present goes under the name of pneumocystis pneumonia

Clinically characteristic of the fatal cases is the fact that the radiological changes, from an early stage in the disease, are of a striking degree and quite out of proportion to the symptoms and signs There is a complete lack of response to antibiotics, and later an increasing oxygen starvation Laboratory methods do not yet give any real help in diagnosis, though Vivell (1954) and Navratil et al (1954) have claimed good results with complement fixation tests using extracts of lung from proven cases Braestrup (1956), however, thinks that there is little to be gained clinically by further diagnostic analysis during life We can liken the situation to that

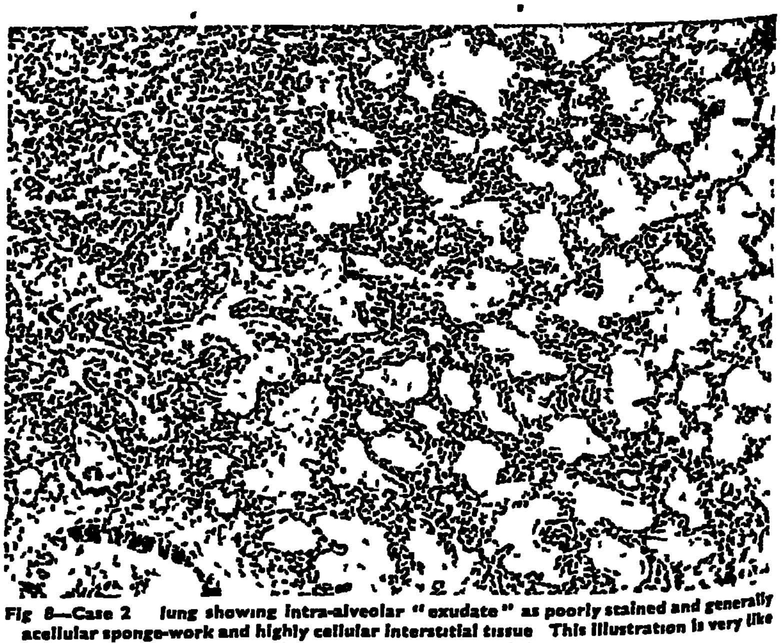

Fig 8—Case 2 lung showing intra-alveolar "exudate" as poorly stained and generally acellular sponge-work and highly cellular interstitial tissue This illustration is very like fig 3 of Hutchison (1955a) (Hæmalum and eosin × 70)

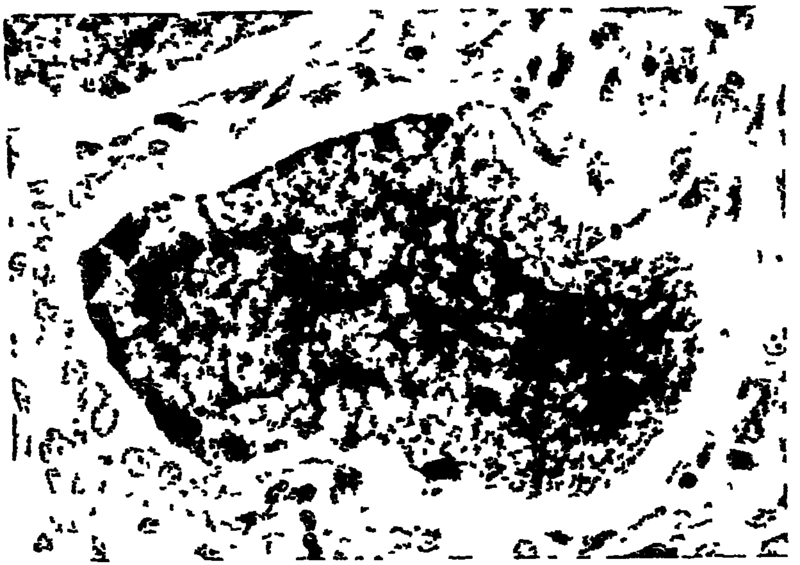

Fig 9—Case 2 details of intra-alveolar honeycomb and its constituent cysts. Note prominent alveolar lining (Periodic acid-Schiff × 479)

of leprosy thirty years ago, where the morbid anatomy was clear cut and accurately indicated the diagnosis, an organism was known but could not be satisfactorily incriminated, and treatment was both empirical and ineffective

Ætiology and Therapy

The only practical knowledge yet available is the reported occurrence of epidemics among infants in hospital, and the Continental workers believe that prophylactic segregation is of value (Reiseterbauer and Braun 1955, Hamperl 1956b) Tobler (1956) claims that the disease has been eliminated in his unit in Switzerland by the use of ultraviolet ray sterilising-lamps in the nursery cubicles for premature infants Many agents have been tried in treatment of the established disease, but the value of none has been confirmed The antiprotozoal drugs (pamaquin, mepacrine, emetine, and organic arsenicals) have been commended by Vanek et al (1953), fungicidal drugs by Petersen (1953), and chloramphenicol by Eberle et al (1955) Gamma-globulin has also been recommended (Sternberg and Rosenthal 1955), but this, like the other therapies, proved of no value in our hands

Morbid Anatomy of the Lungs

The original descriptions of interstitial plasma-cell pneumonia were not very sharply drawn and did not separate it from non-specific chronic inflammation The recognition of the peculiar character of the intra-alveolar exudate (Ammich 1938, Benecke 1938, Vanek and Jirovec 1952) now allows a definite diagnosis to be made post mortem Having observed two cases in Dundee within a short time, we naturally wondered how many cases had been missed After all, this is a widespread disease on the Continent and Switzerland, with its population of 7 million, had 700 cases in 1941–49 (Deamer and Zollinger 1953), while Jirovec (1954) estimates the number of cases in middle Europe at about 500 in 1951–53 A study of 218 infantile cases of pneumonia coming to necropsy in Dundee in 1935–55, and of the comparable cases in Newcastle upon Tyne in 1945–51, did not reveal a single example Baar's experience in Birmingham (Baar 1955) also suggests that the disease is new to Britain

Intensive study of the intra alveolar "exudate" as the probable site of the infective agent has produced a sharp division of opinion On the one hand, there is strong support (Hamperl 1952, 1956a and b, Herzberg et al 1952, Le Tan Vinh 1954, Baar 1955) for the view of Jirovec and Vanek (1954, 1956) that the "exudate" is a mass of protozoa (*Pneumocystis carinii*) On the other hand is the view that the infection is fungal Csillag and Brandstein (1954) favour blastomyces, whereas Simon (1953) believes it to be an unusual form of candida occurring in debilitated people The most likely is perhaps saccharomyces (Bruns and Bottger 1955), which Schmid (1955) believes to be able to form not only the intra alveolar masses but also the cyst like structures which supporters of pneumocystis claim to confirm their view Saccharomyces has been grown by Schmid (1955) from cases with this curious sponge-work in their alveoli, but the pneumocystis has not been cultured or transmitted or defined in any way other than by visual observation of smears, imprints, or sections

Pneumocystis carinii

This protozoon was described first by Chagas (1911) and later by Carini and Maciel (1915) in the lungs of guineapigs infected with *Trypanosoma cruzi and T lewisi* It was later seen by Delanoe and Delanoe (1912) in the lungs of rats without trypanosomes, these workers recognised that this was a separate organism and named it *Pneumocystis carinii* (Wenyon) The cycle of pneumocystis has been studied extensively by Vanek et al (1953), who describe it as a round or an oval mass of chromatin, 1–3 μ in diameter, enclosed in a mucous capsule 5–10 μ in diameter The organism reproduces by division into 2, 4, 6, and finally 8 spore-like structures within a thickened cyst-wall The hosts now known include rats, mice, dogs, cats, goats, and sheep, and the distribution is world-wide

Pneumocystis carinii has been found in the lungs of adult humans with pneumonia associated with Hodgkin's disease (Vanek 1952), myeloid leukæmia (Jirovec and Vanek 1954), and cytomegalic inclusion disease (Hamperl 1956a) In a fourth adult it was found without pneumonia (Van der Meer and Brug 1942) It has also been found in older children aged 5 years by Dr Pavlica (Prof J Vanek, personal communication) and 2 years (Le Tan Vinh 1954) dying with pneumonia in association with neoplastic disease of the reticulo endothelial system.

Most of the Continental workers (Le Tan Vinh 1954, Hamperl 1956a, Jirovec and Vanek 1956) favour the pneumocystis as the causal agent of this peculiar pneumonia of infants

The evidence incriminating *Pneumocystis carinii* is not, in our view, complete enough to absolve other organisms—e g, a fungus such as saccharomyces Our reason for using the name "pneumocystis" in the title of this paper is our inability to coin a more neutral adjective which would be familiar to those who have already studied the disease, would indicate this very specific anatomical change, and would be as easily pronounced

Associated and Predisposing Abnormalities

The disease is almost confined to infancy, and most of the infants affected have been premature, immature, or otherwise weakly There seems to be no special seasonal prevalence The rarity of cases after the first 6 months of life, and the odd fact that the reported adult cases all had a disease involving the reticulo-endothelial system, naturally suggest that an alteration of plasma-globulins has some predisposing influence

The plasma gamma-globulin level is known to be lowest in the normal infant at about the 3rd month, thereafter the waning of the supply received from the mother is countered by intrinsic formation It is not known whether the weakly infant has a longer period of diminution of circulating gamma globulin Infants with pneumocystis pneumonia do not show a serum-protein pattern different from that in unaffected controls (Vanek 1956), but Vanek (1956) does not mention the subdivisions of the gamma globulins, and perhaps antibody activity is particularly localised in the subfraction gamma 2 (Martin 1954) The suggestion of a relation between plasma proteins and pneumocystis pneumonia (Gormsen 1950) was reinforced by Baar's (1955) recognition that the lung illustrated in Hutchison's (1955a) report of a case of congenital agammaglobulinæmia was that of pneumocystis pneumonia This observation gains significance by the finding in case 2 of an almost complete absence of gamma-globulin from the plasma In our other case, and in Hutchison's (1955a) first case the plasma-proteins were unfortunately not estimated, but the fact remains that of the four cases of pneumocystis pneumonia observed in Scotland, two had so-called agammaglobulinæmia

Diminution of gamma globulin therefore seems likely to be a significant predisposing factor in the development of pneumocystis pneumonia Indeed it is possible that the four cases in Scotland occurred because the infants had exceptionally little gamma-globulin In two of the cases there was no estimation to support this view, but all four infants were males, and congenital agammaglobulinæmia (strictly speaking it is hypogammaglobulinæmia) is perhaps confined to males (Good and Zak 1956), and sections from Hutchison's (1955a) patients, aged 6 months and 20 months, which Dr A M MacDonald, pathologist to the Royal Hospital for Sick Children, Glasgow, was kind enough to send us, show the same virtual lack of plasma cells as do the Dundee cases In both these respects the Scottish cases are unusual, because on the Continent the sex-incidence is equal in pneumocystis pneumonia, and the cellular infiltrations are composed mainly of plasma cells, a deficiency of plasma cells is known to be characteristic of congenital hypogammaglobulinæmia The absence of hæmagglutinins in the two present cases adds further support to this view (Good and Zak 1956) The case reported by Dauzier et al (1956) was in a boy aged 21 months, and the history of recurrent pyogenic infections of the respiratory tract suggests that this was a comparable case, unfortunately there is no mention of the serum-proteins

We do not wish to emphasise unduly the suggestion that all four cases were examples of this congenital inability to form gamma-globulin, but the two proven cases raise another interesting point Usually hypogammaglobulinæmia in infants is characterised by recurrent bacterial infections, especially of the respiratory system and the skin (Bruton 1952, Good and Zak 1956), and these pyogenic infections have been controlled by intramuscular administration of gamma globulin On the other hand, in all four Scottish cases there was, at necropsy, a remarkable absence of any sign of pyogenic infection, and we suggest that the organisms in the alveolar spongeworks, be they protozoa or fungi, may have been producing some substance inhibiting pyogenic bacteria Admittedly antibiotic therapy had been given, but in Hutchison's (1955a) first case and in one of ours the disease was well established before such therapy was begun

Conclusion

The disease widespread in Central Europe and known originally as interstitial plasma cell pneumonia of infancy is now recognised as an intra-alveolar infection due either to a protozoon, *Pneumocystis carinii* or to a fungus, possibly saccharomyces

Five cases have now been reported in Britain of what we may in the meantime reasonably call pneumocystis pneumonia If this disease is becoming more prevalent, increasing awareness of the possible diagnosis in atypical pneumonias of infancy may lead to more definite information about the cause

Summary

Two fatal cases of pneumocystis pneumonia in infant are described Of the four now reported from Scotland, two showed extreme deficiency of gamma globulin ("agammaglobulinæmia"), and three of the infants were older than is usual in the Continental cases

Pneumocystis pneumonia is characterised clinically by progressive tachypnœa, dyspnœa, cyanosis, and minimal clinical signs with gross radiological changes On this basis we made a confident provisional diagnosis in one case *during life*

Histologically the changes agree closely with those seen in the interstitial plasma cell pneumonia of the European Continent

Intra alveolar networks and cysts are present, identical with those described by some as the causal protozoön, *Pneumocystis carinii* and by others as a pathogenic fungus

Attempts to isolate the causal agent were unsuccessful

We are grateful to Prof A C Lendrum for his help and criticism during the preparation of this paper Our thanks are also due to Mr J W Corkhill for the illustrations, to Sister M D Crichton for her special care of the infants, and to all those colleagues mentioned in the text, who have been most generous with their help

THE SLUDGING OF BLOOD IN THE RETINAL VEINS

A LITTLE-KNOWN PHYSICAL SIGN

P J D Snow
M.D Manc, M R C P
SENIOR REGISTRAR, THE UNIVERSITY DEPARTMENT OF MEDICINE MANCHESTER ROYAL INFIRMARY

With illustrations on plate

It is the purpose of this paper to call attention to an ophthalmoscopic sign consisting of visible sludging or clumping of the red cells in the retinal veins when the blood-flow has been slowed by pressing on the eye The sign is non-specific, but, since it is usually associated with organic disease, its presence may be helpful in prompting further investigation of patients who are thought to have no organic disease or who have an unconvincing history and physical signs

Elicitation of Sign

The vessels at the optic disc are viewed through an ophthalmoscope, and pressure is exerted with the thumb of the free hand on the lateral aspect of the upper eyelid Usually the pressure causes slight medial movement of the eye, but with a little practice distortion of its shape, which interferes with ophthalmoscopy, can be avoided The pressure required is only enough to induce partial diastolic collapse in the retinal arteries Attention is transferred to the retinal veins, where, if the sign is positive, the column of blood becomes at first granular and then forms into larger discrete particles which move slowly towards the disc (see figure) The time required for these to become obvious is usually about 5–8 seconds, and there is no point in prolonging the pressure if no response has been elicited The rate at which the clumps pass along the veins varies with the pressure on the eye, but, as soon as flow speeds up, they immediately disintegrate

After fairly lengthy pressure a slightly granular appearance in the retinal vessels may be induced even in some apparently healthy persons (particularly in women during menstruation), but only the formation of separate coarse granules is considered to have pathological significance

In practice there is usually little doubt as to what constitutes a positive result, indeed it is not until some familiarity with the sign has been established that lesser degrees of granularity are appreciated

Results

The present series comprises 90 patients in whom sludging was seen by me on one or more occasions That sludging occurs only in certain conditions is shown by the fact that it was not seen in 31 healthy people (15 males and 16 females) or in 150 outpatients with the following disorders

Disorder	*No of cases*	*Disorder*	*No of cases*
Functional disorders	33	Angina of effort	6
Peptic ulcer	17	Infection of renal tract	6
Neoplasm	9	Hiatus hernia	5
Chronic bronchitis	8	Miscellaneous	51
Spondylosis	8		
Hypertension	7	Total	150

Because of the obvious similarity of the phenomenon to the erythrocyte sedimentation rate (E S R), and since it was first seen by me in multiple myelomatosis, both the E S R and the serum globulin level were estimated to discover whether they had any relation to sludging, and also to provide objective indices of abnormality other than the clinical impression of disease

The E S R was estimated by Wintrobe's (1946) method, the upper limits of normal being taken as 12 and 20 mm in one hour for males and females respectively, and the serum globulin was estimated by Reinhold's (1953) method, the upper normal limit being 3 5 g per 100 ml

Of the 90 patients with sludging 79 had definite organic disease, as follows

Disease	*No of cases*	*Disease*	*No of cases*
Active tuberculosis	17	Systemic lupus	3
Carcinoma	10	Reticulosis	3
Cirrhosis	6	Leukæmia	2
Bronchiectasis	6	Myocardial infarction	2
Myelomatosis	5	Ulcerative colitis	2
Pyrexia of undetermined origin	5	Miscellaneous	10
Pneumonia	4		
Rheumatoid arthritis	4	Total	79

In 11 no disease was found 62 patients had raised E S R —above 30 mm in one hour in 49 of them In 5 no figures were obtainable 55 patients had raised serum-globulins —above 4 g per 100 ml in 35 of them Either or both the E S R and the serum-globulin were raised in 73 patients

Of the 11 patients who had no definite organic disease all had normal E S R, and all but 1 had a normal serum-globulin 2 of these 11 patients were pregnant, and another was first seen during the puerperium Sludging was not present in this latter patient when reviewed three months later Ploman's (1920) studies of this phenomenon were made mainly on pregnant women, and I have seen it in pregnancy on several occasions, so probably the effects of pregnancy were responsible for the sludging in the 2 pregnant women mentioned above

4 other patients, reviewed at intervals varying from three to twelve months, showed no alteration in the sludging or any satisfactory explanation of it, but 1 of them had serum-globulin levels of 3 9 and 3 6 g per 100 ml over an interval of twelve months

4 other patients did not attend for review, but 1 of them was known to be menstruating when seen, and this may explain the sludging, because I have observed it during menstruation in some (but not all) healthy women who do not show it during the intermenstrual period

Of the 90 patients in the series, therefore, there were only 7 in whom no explanation for the sludging has yet been found

Discussion

Agglutination of the formed elements of the blood in the retinal veins into macroscopically visible particles was observed by Reimar (1899), who did not correlate the phenomenon with the patient's disease Independently of this observation, Fahraeus, as a result of his studies on the suspension stability of the blood, suggested to Ploman the possibility of observing rouleaux formation in vivo in the retinal veins Ploman (1920) confirmed this and correlated the rate of formation of visible " clumps " with the E S R, but since then there seems to have been no further interest in the phenomenon in the retinal veins, although Wintrobe (1946) mentions its occurrence in myelomatosis An extensive literature, summarised by Knisely (1951), has, however, accumulated on the sludging of blood in conjunctival and similar capillaries This is almost certainly the same phenomenon as that observed in the retinal veins, but, because of the relatively elaborate apparatus required and ill-understood significance of sludging in vessels of this size, it has little clinical application at present

Sludging in the retinal veins, on the other hand, is easily elicited and, being apparently much less sensitive than its capillary counterpart, has some clinical value

The phenomenon is essentially qualitative, for, although Ploman tried to make it semiquantitative by timing the appearance of agglutinated particles, this is actually impracticable because they do not suddenly appear but build up gradually with no definite end-point Moreover their rate of formation is affected by the rate of blood-flow and hence by the variable pressure on the eye

I shall not here consider the factors responsible for sludging, and the E S R and the serum-globulin estimations were mainly in the hope of providing objective indices of abnormality other than the clinical impression of disease In fact the E S R and/or the serum-globulin levels were raised in about two-thirds of the patients, but both were also found raised in the absence of sludging, and the relation is evidently not close A better correlation existed between sludging and the clinical condition, and sludging sometimes seems to be a more sensitive index of disease than either of these laboratory tests

It must be admitted, however, that apparently false positive results may occur, for 11 of the patients had no obvious disease, although pregnancy in 2 and menstruation in 1 of these was almost certainly responsible

It should also be emphasised that not all diseases are associated with sludging, and that its absence does not imply the absence of organic disease

The value of the test is therefore limited, but, if pregnancy and menstruation are excluded as causes, the large majority of patients showing sludging will be found to have organic disease

A surprising feature was the high proportion of patients who turned out to have either active tuberculosis or cancer, and it is clear that sludging may occur in a wide variety of diseases other than myelomatosis, which, so far as I know, is the only specific disease in which sludging in the retinal veins has hitherto been described (Wintrobe 1946)

In most patients the presence of organic disease was all too obvious and did not need confirmation 14 patients, however, had complaints which were thought at first to be functional or of a simple non inflammatory nature, and the finding of sludging suggested further investigations, which in each case disclosed a more serious unsuspected lesion, usually tuberculous or neoplastic

The following 3 case reports illustrate this application of the sign

Case-reports

Case 1 —A man, aged 25, presented with a four week history of severe sciatic pain attributed to a prolapsed intervertebral disc The presence of sludging, however, was not in keeping with a purely mechanical cause for his pain, and further investigation revealed tuberculosis of the right sacro iliac joint

Case 2 —A woman, aged 28, was admitted with hæmatemesis Sludging was noted after she had recovered from this and did not seem to be adequately explained by a peptic ulcer Radiography revealed a gastric ulcer and active pulmonary tuberculosis

Case 3 —A man, aged 55, presented with left sided chest pain for which no cause was at first found Radiography was normal At a second attendance a month later sludging was observed, and the patient was admitted for further investigation, which disclosed erosion of the pedicle of the fourth thoracic vertebra, not previously present and eventually found to be due to a metastatic adenocarcinoma

Summary and Conclusions

Sludging or clumping of the red cells in the retinal veins when the blood stream is slowed was observed in 90 patients It was found almost exclusively in certain diseases, or in pregnancy and (to a lesser extent) during menstruation It was sometimes associated with a raised erythrocyte sedimentation rate and a raised serum-globulin level, but it may occur independently of either Its sphere of usefulness is similar to that of the E S R, for it appears to be a fairly reliable indication of organic disease It can, however, be elicited immediately and has been found to be particularly useful in bringing to light unsuspected organic disease in patients with few or unconvincing symptoms

I wish to thank Prof Robert Platt and Dr H T Howat for permission to study their patients

The serum cholesterol level in man can be lowered by substitution of carbohydrate for the common meat and dairy fats in the diet, and this effect does not depend on the intake of cholesterol itself (Keys 1953, 1954, Keys et al 1950, 1955, 1956) Different food fats, however differ in their effect, and certain vegetable oils may depress the serum cholesterol level (Ahrens et al 1954 Bronte Stewart et al 1956, Friskey et al 1955, Kinsell et al 1952)

Ahrens et al (1955) found corn (maize) oil particularly effective, and they suggested that the effects of dietary fats on the serum cholesterol level in man depend on the relative degree of saturation of their constituent fatty acids But corn oil has a relatively high content of the "essential" fatty acid linoleic acid, so it is intriguing to speculate on whether hypercholesterolæmia is an expression of a deficiency of essential fatty acid in the diet—a deficiency that could be corrected by the consumption of a fat, such as corn oil, rich in linoleic acid (Bronte-Stewart et al 1956, Kinsell et al 1956, Sinclair 1956)

One result of such considerations is enthusiasm for food fats even richer in linoleic acid, and/or more unsaturated than corn oil, as agents for combating hypercholesterolæmia and so, it is hoped, for preventing atherosclerosis and coronary heart-disease We have urged caution about premature conclusions in this direction (Keys 1953), but already there is commercial interest in sunflower seed oil, as a very rich source of linoleic acid, and in fish oils as the most unsaturated of the food fats The fish industry is heartened by imaginative statements that coronary heart disease is absent in Eskimos and rare in Norwegians because of their consumption of marine oils (Sinclair 1956), though actually the incidence of coronary heart disease among Eskimos is entirely unknown and the disease is anything but rare in Norway

Fish oils contain little or no linoleic acid and only minute amounts of arachidonic acid, so, if they were in fact more effective than corn oil in reducing serum cholesterol this would support the view that unsaturation is responsible If, on the other hand, sunflower seed oil were more powerful in decreasing blood cholesterol, this would suggest that linoleic acid is the active agent Obviously a direct comparison between corn, sunflower, and fish oils is essential

Present Experiments

We have examined these and related questions in dietary experiments with physically healthy men in a completely controlled metabolic research unit of the Hastings State Hospital, and present here a summary of data on corn oil versus sunflower seed oil, corn oil versus fish oil, and a final comparison with butter fat, as regards

TABLE I—CHARACTERISTICS OF OILS TESTED

Item	Corn oil	Sunflower-seed oil	Sardine oil	Butter fat
Iodine number	120	131	188	32
Linoleic acid content	45%	61%	0–2% (?)	3%

the serum-cholesterol level Characteristics of the oils used are given in table I The iodine numbers were determined in this laboratory, and the linoleic-acid content values are those published for samples of these fats of similar iodine number

The test oils were fed in quantities of 100 g daily as part of a diet constant in all other respects and designed to provide an average of 100 g of proteins, 300 mg. of cholesterol and 40 g of mixed food fats in addition to the test oil Calorie balance was maintained by individual adjustments in bread and jelly, and a fixed level of physical activity was maintained throughout The subjects were 26 schizophrenics selected for physical health, metabolic normality, and demonstrated cooperativeness

Before the experiments with these oils the men were all maintained at calorie balance on a fixed diet for several months, including a stabilising period of four weeks with 100 g of butter fat The men were divided into four groups matched as to age, relative obesity, and habitual level of voluntary activity. The design of the experiment with the test oils is shown in table II Groups W and X contained 7 men each, and groups Y and Z contained 6 men each

The mean values of the four groups for age, initial and final body-weights, and daily consumption of calories are given in table III For the entire 26 men the mean body-weight changed only by 0 19 kg from the start to the end of the tests, demonstrating the accuracy of the calorie equilibrium maintained by the diets

TABLE II—EXPERIMENTAL DESIGN FOR FEEDING CORN OIL, SUNFLOWER SEED OIL, SARDINE OIL, AND BUTTER FAT

Inclusive dates	Group			
	W	X	Y	Z
June 8–21	Corn	Sunflower	Corn	Sardine
June 22–July 5	Sunflower	Corn	Sardine	Corn
July 6–21	Butter	Butter	Butter	Butter

Samples of blood were drawn at the end of each week and analysed for serum total-cholesterol (in duplicate) and the cholesterol in the α and β lipoprotein fractions of the serum, separated by paper electrophoresis The methods have been described by Anderson and Keys (1956) Here, for the sake of brevity, it is enough to consider only the mean blood-cholesterol levels at the end of the second week on each diet, the levels at the end of the first week are similar and show, as we have found before (Keys et al 1950), that a large part of the cholesterol response to a change in diet is produced in the first week

TABLE III—MEAN VALUES FOR EXPERIMENTAL GROUPS JUNE 8–JULY 21

Item	W	X	Y	Z
Age (yr)	46 4	46 8	48 4	48 7
Initial body weight (kg)	69 7	67 3	65 7	66 2
Final body weight (kg)	70 0	67 1	66 2	66 6
Intake of calories daily	3375	3391	2922	3074

Results

The average serum cholesterol level on the butter-fat diet was 216 9 mg per 100 ml All the groups had significantly lower serum cholesterol levels on the corn-oil diet, the average difference being 45 1 mg per 100 ml for the W and X groups and 60 0 mg for the Y and Z groups The serum cholesterol levels were also lower on the sunflower seed-oil diet ($\Delta = 35$ 8 for W and X groups) and on the sardine oil diet ($\Delta = 39$ 8 for Y and Z groups) These differences were primarily due to changes in the β-lipoprotein-cholesterol level The most interesting results, however, are for the direct crossover comparisons summarised in table IV

In the change of 7 men from corn oil to sunflower-seed oil, and in the reverse change made simultaneously with the other 7 men, the serum total-cholesterol was higher on the sunflower-seed oil than on the corn oil, the difference being statistically significant at about the 1% level of probability In groups Y and Z the serum cholesterol level was higher on sardine oil than on corn oil, the difference being highly significant ($t = 5$ 38, and, at 11 degrees of freedom, $P < 0$ 001) As in the case of the comparisons with butter fat, the cholesterol in the β-lipoprotein fraction seems to be primarily involved in the total cholesterol differences, the percentage of the total cholesterol found in the β fraction tends to be lowest when the men are on the corn-oil diet

TABLE IV—DIFFERENCES IN SERUM TOTAL CHOLESTEROL LEVEL AND IN PERCENTAGE OF TOTAL CHOLESTEROL IN THE β-LIPOPROTEIN FRACTION OF SERUM

Diet comparison	No of men	Total cholesterol (mg per 100 ml)	% of total cholesterol in β lipoprotein
Corn-sunflower	14*	−9 29 ±2 81	−1 08 ±2 16
Corn-sardine	12	−20 17 ±3 75	−4 25 ±1 34

* For total cholesterol 12 men only for β-lipoprotein (one value missing in each of the groups W and X)

The net result is that both sardine oil and sunflower-seed oil are more, rather than less, cholesterol-increasing than is corn oil Or, to put it the other way round, corn oil has the greatest cholesterol-depressing effect of the fats tested The attempt to discover whether the high content of essential fatty acids or the high degree of unsaturation is responsible for the cholesterol depressant action of corn oil had the surprising result of showing that corn oil is remarkable in some way not measured by either of these two characteristics

Discussion

While the above findings were being belatedly summarised for publication, Jones et al (1956) reported, in cholesterol-fed chicks, an anti cholesterol effect of corn oil, and still more so of corn germ, and provided evidence that this effect cannot be explained on the basis of the fatty acid composition of the oil The results of other experiments on animals had cast serious doubt on the validity of both the unsaturation and the essential-fat hypotheses of the control of the serum cholesterol level (Lin et al 1955, Swell et al 1955) Unfortunately the differences between animal species in the metabolism of fat and cholesterol make it dangerous to extrapolate from such experiments to man It is not possible to state, for example, what may be the relevance to man of the interesting observation that rabbits fed a diet high in peanut oil but low in saturated fat and devoid of cholesterol slowly develop progressive hypercholesterolæmia and, within a year, atherosclerosis (Steiner and Dayton 1956) Perhaps this finding is most significant as a warning against judging the ultimate cholesterogenic and atherogenic effects of diets on the basis of short time experiments

It is interesting to ask what may be the relevance of the present experimental findings to the fact that low serum-cholesterol levels are characteristic of human populations who habitually subsist on low-fat diets (Keys 1953, 1954, Keys et al 1955) Are such low serum-cholesterol levels explained by the low-fat diets, or do relatively high intakes of essential or highly unsaturated fatty acids contribute to the picture? The intake of linoleic or combined polyethenoic fatty acids in the average American diet is about twice that in the typical low-fat diets of Japan and Italy, which are associated with average serum cholesterol levels of only about 150–200 mg per 100 ml No natural human diets approach the situation of the present experiments where 50–60 g of linoleic acid was ingested daily (in the experiments with corn oil and sunflower-seed oil) or where fish oils accounted for nearly 30% of the total calories Even among the fish eating Japanese no more than 2–3% of the total calories is supplied in the form of fish oils

As populations increase the fat content of their diets, they do so by consuming more saturated *and* unsaturated fats, though the increase in the latter is smaller It seems, then, that among most of the populations of the world the characteristic serum-cholesterol levels are directly related to the total consumption of fat rather than inversely related to the consumption of essential or highly unsaturated fatty acids And, if we are to advocate dietary alterations on a population scale to control the serum cholesterol level, it seems wiser to attempt to reverse the trend towards more and more luxurious high-fat diets than to advise consuming more vegetable and fish oils as a counter measure But in so far as there is simply a choice of the kind of fat to be used, corn oil may have special virtue

Summary

Serum total and β-lipoprotein cholesterol levels were measured in rigidly controlled experiments on 26 men in calorie balance on a diet constant in all respects except for the character of test fats—corn oil, sunflower seed oil, sardine oil, and butter fat—which were fed in quantities of 100 g daily Other mixed food fats in the diet amounted to 40 g daily, and total fats represented 39 8% of the total calories

The mean serum total cholesterol level on the butter-fat diet was 52 0 mg per 100 ml higher than on the corn-oil diet, 35 8 mg higher than on the sunflower seed oil diet, and 39 8 mg higher than on the sardine oil diet

The serum total cholesterol level rose after the change from corn oil to sunflower seed oil and fell after the reverse change, the average difference being 9 3 mg per 100 ml

The serum total cholesterol level rose after the change from corn oil to sardine oil and fell after the reverse change, the average difference being 20 2 per 100 ml

The level of cholesterol in the β-lipoprotein fraction of the serum was primarily involved in the above changes

These findings do not support the view that the serum-cholesterol level in man is a simple inverse function of the essential fatty acid content or of the degree of unsaturation of the fatty acids in the diet

High blood-pressure is one of the commonest and mo t serious complications of all forms of acute and chronic primary renal disease The possible mechanisms involved in the production of such hypertension have recently been reviewed (Wilson 1953) Therapeutic reduction of the blood-pressure is justified by the well established experimental evidence that hypertension may cause renal vascular damage and progressive deterioration in function Secondary hypertensive lesions in the kidney constitute the most serious prognostic factor in certain forms of chronic Bright's disease and probably play an important part in the development of the malignant type of hypertension which occurs in many cases

Within recent years the medical treatment of hypertension has become feasible, following the introduction of different drugs which effectively lower blood pressure Many reports describe the satisfactory use of these drugs, but analysis of these shows little correlation between treatment and the ætiology of the hypertension in the individual case Most are concerned solely with the hypotensive effect of the drugs, and apparently most of the cases of hypertension so treated were of the essential variety without impairment of renal function

Nevertheless a diagnosis of the underlying cause is essential for accurate prognosis and rational therapy The rôle of hypertension varies considerably in different forms of renal disease, and treatment that might be beneficial in some cases may well be harmful in others

The indications for lowering blood-pressure may be classified as symptomatic or prophylactic

Symptomatic indications include heart-failure (both the acute left ventricular and the chronic congestive varieties), encephalopathy, and retinopathy In this paper we have used the term retinopathy to indicate at least the presence of retinal hæmorrhages and exudates We believe that, in renal disease, the appearance of these retinal changes whether or not visual impairment is present, constitutes an absolute indication for lowering the blood-pressure The advent of papillœdema indicates the onset of the malignant phase of hypertension, and, in the absence of therapy, rapid deterioration due to renal vascular damage, heart-failure, or encephalopathy is inevitable Heart-failure may reduce *glomerular filtration* and lead to nitrogen retention in chronic renal disease, *hence* its relief by hypotensive therapy may well lead to improvement in renal function The *prophylactic indications* call for prolonged observation and treatment Here th

aim of therapy is to prevent deterioration in renal function caused by the secondary effects of hypertensive vascular damage to the kidney and to delay the onset of the malignant phase

To assess the results of treatment it is imperative to take into account the natural history of untreated renal hypertension The exact nature of the renal lesion is important for the course and prognosis of different forms of nephritis vary greatly It is important also to estimate the relative contributions of nephritis and hypertension to the progress of the disorder in the individual case

Many patients with chronic renal disease live for years with normal renal function and slight or moderate hypertension Chronic type I nephritis in its slowly progressive course (Ellis 1942), may behave in this way, and so also may chronic pyelonephritis When eventually incapacitating symptoms appear these are usually of hypertensive rather than renal origin After many years of slight or moderate hypertension, a relatively steep rise in blood-pressure commonly occurs, accompanied or followed by a rapid deterioration in renal function If no active steps are taken to reduce the blood-pressure, malignant hypertension supervenes in about half the cases, in the remainder a more slowly progressive uræmia develops Fig 1 illustrates a typical case of this "hypertensive transformation" (Wilson 1955)

Some patients with kidney disease present a different picture In them there is obviously a continuing active glomerulonephritis, indicated by anæmia, microscopic hæmaturia, and frequent granular casts in the urine Here the primary renal condition has evidently a more significant effect on the natural history of the disease than have secondary hypertensive changes Although, in these patients, hypotensive therapy may be necessary to control encephalopathy or retinopathy, the same degree of benefit is not to be expected as in the previous group It is particularly in the more severe cases of type-II nephritis that this progressive inflammatory element is found, and in such cases deterioration of renal function may antedate the terminal rise in blood-pressure

With these considerations in mind we studied the effect on renal function of lowering the blood-pressure in patients with hypertension and renal impairment We wanted, first, to determine whether normotension could be achieved without provoking acute deterioration in renal function; this was readily established in a series of comparatively short-term observations Secondly, patients with renal hypertension were observed for longer periods in an attempt to discover whether the usual deterioration in renal function could be retarded or even halted, and whether the onset of hypertensive complications, particularly the malignant change, could be prevented Thirdly, we were interested to see whether the different types of renal disease described above differed in their response to hypotensive therapy

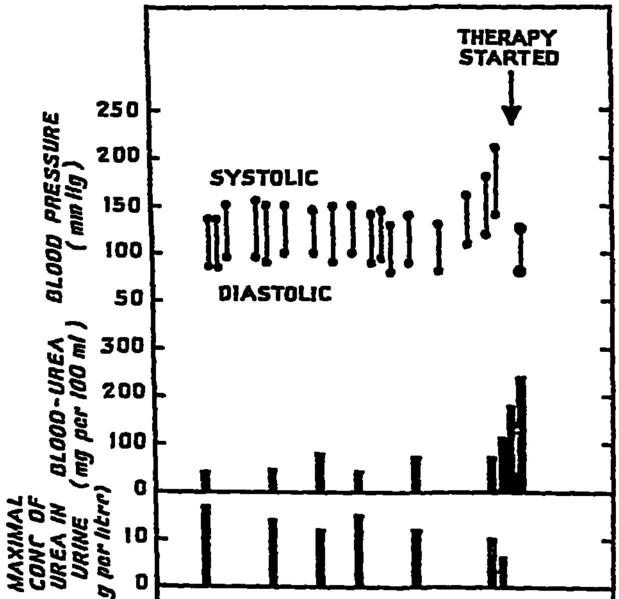

Fig 1—Case 17 chronic type-II nephritis showing rapid deterioration of renal function associated with rise in blood-pressure Although hypertension was controlled, renal failure was progressive

Clinical Material and Selection of Cases

All the patients reported in this series were treated in the nephritis clinic of the London Hospital and selection followed the indications outlined above Treatment was instituted either for the relief of acute hypertensive manifestations, such as heart-failure, encephalopathy, and retinopathy, or for prophylactic purposes In the former group the hypertension was usually severe when the patient was referred to us, and renal impairment and retinopathy were often present In most of these patients the diagnosis was chronic type-I nephritis Patients with type-II nephritis, on the other hand, had usually been under observation for months or years with normal renal function and little or no hypertension This afforded a good opportunity for correlating the development of hypertension with change in the renal function and for starting treatment when the blood-pressure began to rise Some of these patients were free from symptoms when hypotensive therapy was begun

Observations were made on 32 patients—16 with chronic type-I nephritis, 7 with type II nephritis, 4 with other forms of renal disease, and 5 with essential malignant hypertension The last-named are included for comparison with primary renal disease Renal function was impaired in all the cases at the time therapy was begun The clinical details and particular indications for treatment are listed in tables I–IV

Methods

Treatment followed standardised lines Initially ganglion-blocking agents alone were used—always by injection—and pentolinium ('Ansolysen') was the drug of choice More recently we have used reserpine ('Serpasil') in combination with ansolysen by mouth or 'Ecolid' (4 5 6 7-tetrachloro-2-(2 dimethylamino ethyl) iso-indoline dimethochloride) also by mouth All the patients were admitted to hospital for preliminary investigation and initial therapy Their blood-pressures were recorded hourly throughout the day in the standing and lying positions After about a week hypotensive drugs were administered and further blood-pressure curves were obtained, the dosage of the ganglion-blocking agent being gradually increased until an optimal effect was gained

The regime was varied to suit the patient's requirements and idiosyncrasies, sometimes the blocking agent was given twice and sometimes thrice daily, but always at least half an hour before food We found it unnecessary to give more than 1 mg of serpasil daily in divided doses and often 0 25 mg twice daily sufficed In a few cases serpasil alone proved effective, but there appears to be no means of foretelling such a response

Renal function was measured before therapy was started and again after two to four weeks, when optimal lowering of blood pressure had been achieved After discharge from hospital the patients were seen monthly in the outpatient department, and renal function tests were repeated at regular intervals Any cardiac deterioration, or improvement, was checked by serial electrocardiograms and chest radiographs We used the blood-urea level, urine urea concentration, and creatinine clearance as tests of renal function, being well aware of their inherent fallacies

Experience has shown that, in the individual case, this group of tests, performed at regular intervals, satisfactorily indicates the general trend of renal function Reliance should not be placed, however, on any individual reading, for discrepancies arise from variations in urine output, superimposed extrarenal retention of nitrogen, or incomplete emptying of the bladder

Results

Control of Blood pressure

High blood-pressure due to renal disease responds to hypotensive drugs in much the same way as essential hypertension, and there seems to be no greater resistance to therapy Indeed some patients are remarkably sensitive to these drugs, possibly owing to delayed excretion (Harington 1953)

Our results suggest that papillœdema responds more rapidly than in malignant essential hypertension, in all the cases of primary renal disease reported here papillœdema had subsided within a month of treatment being started

Most patients with malignant essential hypertension require larger doses of hypotensive drugs than are needed to control renal hypertension We have rarely had to give more than a total of 200 mg daily of ecolid by mouth together with 0 5–1 0 mg of serpasil, and normotension has often been attained with a lower dosage In our cases of essential malignant hypertension 400 mg of ecolid daily has sometimes proved insufficient, even when combined with serpasil, and papillœdema has been correspondingly refractory

We believe that the blood-pressure should be brought as near normal as possible in all cases, the dose being progressively increased to the limit of the patient's tolerance

Immediate Effect of Lowering Blood-pressure on Renal Function

In tables I–IV are listed the renal function and blood pressure immediately before treatment, and again after two to four weeks in hospital, when optimal control of blood-pressure had been achieved Such observations were available in 14 patients with chronic type I nephritis The blood-urea level did not change significantly in 10 cases, rose in 3, and fell slightly in 1 The other tests of renal function showed substantially the same results In

the great majority of cases of type-I nephritis, therefore, hypotensive therapy had no immediate harmful effects

The same may be said of the results obtained in renal hypertension from causes other than nephritis (table II, cases 24–27) and in malignant essential hypertension (table III, cases 28–32) There was no evidence in these groups that lowering the blood-pressure was detrimental to renal function, and neither the age of the patient, the sex, the degree of hypertension, nor the extent of renal impairment at the start of therapy seemed to make any difference to the result

In type-II nephritis, however (table IV, cases 17–23), the results were somewhat different There were 7 patients in this category, and in 4 the renal function was definitely worse after this short period of treatment, whilst in 3 it was unchanged 1 patient (case 17) died in uræmia two months after therapy was begun Lowering of the blood-pressure probably played little part in this deterioration, for in all 4 cases where it was observed there had been a rapid worsening of renal function just before treatment was started This sequence is illustrated in fig 1 It seems likely that, in these cases, renal failure was the result of severe progressive glomerulonephritis

TABLE III—SHORT TERM RESULTS OF HYPOTENSIVE THERAPY IN MALIGNANT ESSENTIAL HYPERTENSION WITH RENAL IMPAIRMENT

Long term Results

The long-term results of therapy lend themselves less readily to analysis than the short-term Only those patients who were treated with hypotensive drugs for at least six months have been included, and for several reasons these are few

When treatment was started, many patients were seriously ill, with poor renal function, very high blood-pressure, and other serious complications, 3 died in uræmia in less than six months (cases 3, 17, and 24) Moreover several patients, especially those who were treated for prophylactic reasons, were unwilling to persevere with a treatment which produced unpleasant symptoms Thus 6 abandoned treatment and have been excluded (cases 9, 11, 15, 16, 23, and 27) In addition 7 patients have not yet been treated for six months (cases 2, 8, 10, 19, 21, 25, and 29)

A further complicating factor is the variable degree of control of the blood-pressure in the individual case, for, though normotension was readily obtained during the initial period of treatment, the blood-pressure often rose after discharge from hospital This may have been due either to acquired tolerance to the drug or to lack of

cooperation We encouraged all the patients to return to a normal active life, and increased physical activity may have diminished their response to hypotensive drugs In some patients dosage was satisfactorily readjusted, in others this was impossible, and we had to be content with a suboptimal lowering of the blood-pressure

The control of blood-pressure during long-term treatment was classified as good if the blood-pressure fell to 150/100 mm Hg or below in the standing position, poor if the diastolic pressure was persistently above 120 mm Hg, and fair between these extremes

16 patients were treated for six months or longer (table V) The diagnosis in 8 of these was chronic type I nephritis, in 3 type II nephritis, in 1 chronic pyelonephritis, and in 4 malignant essential hypertension Of the patients with type-I nephritis, renal function improved in 2, remained unchanged in 2, and became worse in 4

The period of treatment varied between seven and twenty-four months, and, not unexpectedly, the degree of renal impairment at the start of therapy was important in prognosis

An example of a good therapeutic response is shown in fig 2 In the 4 patients whose renal function deteriorated the initial creatinine clearance was low (23–52 ml per minute), the average being just under 34 ml The initial blood-urea level was more variable but was above 70 mg per 100 ml in 3 cases The patient with pyelonephritis (case 26) showed persistent improvement in renal function after seven months' therapy, but there was only slight renal impairment when treatment was started

4 patients with malignant essential hypertension were treated for periods of six months to four years Renal function has not deteriorated in any Renal impairment was greatest in case 31 (blood urea 73 mg per 100 ml creatinine clearance 56 ml per minute), in the other 3 patients it was only slight

2 of the 3 patients with type II nephritis showed deterioration in renal function after treatment for twenty six and six months, both had grossly impaired renal function at the onset (creatinine clearances 27 and 18 ml per minute) In the 3rd patient the creatinine clearance was initially 50 ml per minute, and treatment has been maintained for nine months without apparent deterioration With 1 exception, patients in any group who showed no deterioration of renal function on prolonged hypotensive therapy had an initial creatinine clearance of 50 ml per minute, or more (range 25–100 ml average value 67 ml)

Mortality

There were 3 deaths in this long term series, all examples of chronic type I nephritis

One patient, in whom papillœdema was initially observed, died of cerebral hæmorrhage after eighteen months, during which time control of blood-pressure was considered poor (case 7) A cerebrovascular accident was the cause of death in a 2nd patient (case 13), after fifteen months' therapy, with only fair control of blood-pressure, at the beginning of treatment this patient had severe retinopathy and left heart-failure The 3rd patient died from uræmia, after fourteen months' therapy, with fair

TABLE V—LONG-TERM EFFECTS OF HYPOTENSIVE THERAPY ON RENAL FUNCTION

Case no	Sex	Age (yr)	Diagnosis	Renal function				Control of blood-pressure	Comment on renal function

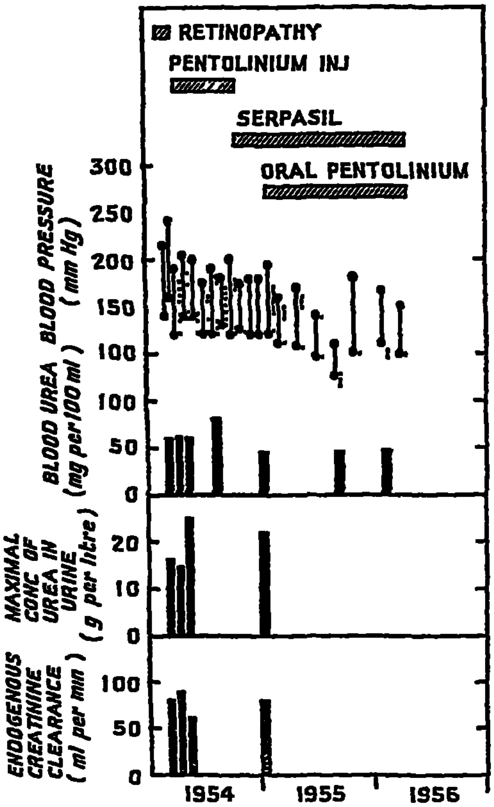

Fig 2—Case 1 chronic type-I nephritis showing sustained control of hypertension by serpasil and pentolinium without further deterioration in renal function over 2 years B-P in lying position is represented by continuous lines, and in standing position by interrupted lines

control of blood-pressure (case 14), here renal failure was advanced when the patient was first seen, and therapy was only undertaken with considerable misgivings for the relief of symptoms

Few conclusions should be drawn from these fatalities, but cerebral hæmorrhage still remains an important cause of death, and here the effectiveness of controlling the blood-pressure may well be important In none of these fatal cases was there a malignant termination—i e, appearance or reappearance of papillœdema was not observed

In the whole series of 32 patients other deaths occurred either before six months' therapy had been concluded or after therapy had been discontinued These fatal cases are considered below

Discussion

Several reports have been published of the pharmacological actions on the renal circulation in man of ganglion-blocking agents and other hypotensive drugs

Mackinnon (1952) found that, both in normotensive subjects and in patients with benign or malignant essential hypertension, pentamethonium iodide reduced the glomerular filtration rate and effective renal blood flow The reduction in renal blood flow was greater than could be explained by the fall in blood pressure—indicating a selective vasoconstrictor effect on the kidney

Similar results were obtained with hexamethonium by Moyer and Mills (1953), the ætiology of the hypertension was not specified

According to Moyer et al (1955) and Andreae and Smith (1955) the rauwolfia alkaloids have no direct effect on renal hæmodynamics

'Apresoline' (hydrallazine) on the other hand increases renal blood flow (Mackinnon 1952), and it therefore appears to be the drug of choice when ischæmic renal disease is present Unfortunately we have found it valueless in chronic renal hypertension

If the above results were applicable to patients with impaired renal function we might expect ganglion-blocking drugs to cause further deterioration, but clinical experience has not substantiated this

Morrison (1953) treated hypertensive patients with parenteral hexamethonium and reported that, of 5 with initially a raised blood urea level, 3 showed no further rise during treatment, and in 2 the observed rise was no more than would be expected in the natural course of the disease

In a series reported by Harington and Rosenheim (1954) 9 patients were treated when the blood urea level was above 40 mg per 100 ml, in 4 of these the level rose with treatment and in 5 it fell These workers concluded that renal disease was no contra indication to treatment with ganglion blocking agents

Our results support these earlier observations Evidently the changes in renal hæmodynamics observed in an acute experiment bear no definite relation to the therapeutic response which follows long-confirmed lowering of the blood-pressure

Ellis (1942), comparing the histological findings in type I nephritis and type-II nephritis, wrote

> "Of special significance is the difference in the chronic stage, for whereas in type 1 nephritis the early lesions give place to secondary hypertensive changes resulting in focal renal destruction, in chronic type 2 nephritis there is a progressive glomerular hyalinisation with diffuse renal destruction in which the hypertensive process appears to play relatively little part"

The results which we report here lend support to this observation, for it was in chronic type-I nephritis that the treatment of hypertension was most satisfactory A similar result might be expected in chronic pyelonephritis In type-II nephritis, on the other hand, where hypertensive vascular damage is not conspicuous and there is evidence of progressive renal destruction from the nephritic process, the results of hypotensive therapy are disappointing

There have been 11 deaths in this series, the 3 which took place after prolonged hypotensive therapy have already been discussed 4 patients died during the first six months of therapy; 2 of these had chronic type I nephritis with severe renal failure (cases 3 and 9) at the start of treatment, the 3rd was an elderly man with a blood-urea of 171 mg per 100 ml due to polycystic disease (case 24), and the 4th was a girl, with very active type-II nephritis, who died in uræmia after three months' treatment (case 17) Thus there were 7 deaths during therapy, in 5 the cause was uræmia and in 2 a cerebral vascular lesion There was no instance of a malignant termination

4 other patients died after they had abandoned treatment (cases 11, 15, 23, and 27) In 2 there was a malignant termination (cases 11 and 23), and 2 died in uræmia without the development of papillœdema (cases 15 and 27)

From these figures it is obvious that hypotensive drug therapy was of little use in the late stages of renal failure The important fact remains, however, that, when renal function was only slightly impaired, adequate control of the blood pressure in patients with chronic type I nephritis or malignant essential hypertension was not accompanied by any serious deterioration in renal function over the period of observation In addition to this possible prophylactic effect, symptomatic improvement was striking in most instances Most of our patients had severe headaches, some had distressing dyspnœa, and some had impaired vision Hypotensive therapy provided relief in such cases and for this reason alone appeared well justified—regardless of the ultimate prognosis

Summary and Conclusions

27 patients with primary renal disease, hypertension, and impairment of renal function, were treated with

hypotensive drugs 5 patients with malignant essential hypertension and renal impairment were included for comparison

The results of therapy depend largely on the initial degree of renal impairment and partly on the type of renal disease Usually cases of chronic type-I nephritis, pyelonephritis, and malignant hypertension showed no deterioration of renal function when the initial creatinine clearance was over 50% and the blood-urea level below 60 mg per 100 ml Renal failure progressed when the initial creatinine clearance was below 30% and the blood-urea above 70 mg In chronic type II nephritis the results are less favourable

Adequate control of the blood-pressure seems to prevent the malignant hypertensive termination in renal disease, but cerebral vascular accidents still happen

Hypotensive therapy had no value in staying the onset of renal failure in type-II nephritis There was no satisfactory evidence that lowering the blood-pressure was responsible for deterioration of renal function in these patients, but that possibility must be considered

The need for accurate diagnosis of the renal lesion, before hypotensive therapy is given, is emphasised

We thank Messrs Ciba for generously providing supplies of 'Ecolid'

RENAL HÆMODYNAMIC EFFECTS OF HYPOTENSIVE DRUGS

I ACUTE EFFECTS OF HEXAMETHONIUM BROMIDE BEFORE AND AFTER TREATMENT WITH RESERPINE

B GOLDBERG
M D Witw'srand, M R C P
LEVERHULME RESEARCH SCHOLAR

From the Institute of Clinical Research and Experimental Medicine, Middlesex Hospital, London

PARENTERAL administration of the ganglion-blocking agents hexamethonium and pentamethonium to hypertensive patients reduces the glomerular filtration-rate, the renal plasma flow, and the excretion of water and sodium The renal vascular resistance tends, as a rule, to increase, but it may decrease during the peak action of the drug as judged by the arterial blood-pressure (McQueen 1952, Mackinnon 1952, Mills and Moyer 1953, Freis et al 1953)

In the work reported here these findings were confirmed and the effect of preliminary treatment with another hypotensive agent, reserpine ('Serpasil'), on the changes induced by hexamethonium were investigated

Material and Methods

Thirteen patients with sustained hypertension were studied Nine were women and four were men, their ages ranging from 24 to 72 One patient had chronic bilateral pyelonephritis (case 6), one had chronic unilateral pyelonephritis (case 3), and in one hypertension was first observed during a pregnancy (case 13) The remainder were considered to be cases of essential hypertension of varying severity with case 7 presenting in the malignant phase of the disease

To attain as basal states as possible the patient had an initial rest period of 2 weeks in hospital, without treatment, before each test (In the patient with malignant hypertension the period of observation was only 6 days, because her condition was deteriorating) All the tests were made at the same time of day, about 3 hours after a light breakfast Water, 1000 ml, was given in the 45 minutes before the start of each test All the measurements were made with the patient recumbent The glomerular filtration-rate (G F R) and renal plasma flow (R P F) were measured by the clearance rates of inulin and *p* aminohippurate respectively, the plasma levels of these substances being kept constant by a continuous intravenous infusion After 45 minutes allowed for equilibration, urine was collected in three periods, each of about 15 minutes, the bladder being emptied by washing with distilled water and air and by suprapubic compression During this time the blood pressure in the arm was measured by auscultation every few minutes, and the pulse rate was recorded After these control observations hexamethonium bromide 5–45 mg was injected via the infusion tubing, and observations were continued during three further periods

C, D E F, as in table I.

of about 15 minutes each An attempt was made to estimate by a previous test dose the amount of hexamethonium necessary to produce a moderate fall in blood-pressure in each patient

Inulin in the plasma and urine was measured by the method of Roe et al (1949), and *p* aminohippurate by the method of Smith et al (1945) Urinary sodium and potassium concentrations were determined by flame photometry The mean arterial blood-pressure (M B P) was estimated as one third of the pulse pressure plus the diastolic pressure, and the renal blood-flow (R.B F) was calculated as $\frac{\text{Renal plasma flow}}{1\ \text{Hæmatocrit}}$

The renal vascular resistance (R V R) was expressed as units of $\frac{\text{M B P}}{\text{R B F}}$ The G F.R, R P F, and R V.R were corrected for a body-surface area of 1 73 sq m

In five of the thirteen patients (cases 9–13) the above-mentioned procedure was repeated after 2 weeks during which oral reserpine 0 5 mg t i d was given The dose of hexamethonium administered to each patient on the second occasion was the same as that given during the first test

Results

The results in the thirteen patients after the injection of hexamethonium are shown in table I Table II shows the effects of hexamethonium in the five patients during treatment with reserpine Fig 1 illustrates the changes induced by hexamethonium in the thirteen patients, and fig 2 the changes induced by hexamethonium in one patient before and during treatment with reserpine

The average blood pressure was 203/122 mm Hg before the injection of hexamethonium After injection the pressure fell in most cases to an average of 160/105 There were, however considerable individual differences in the response to hexamethonium the blood pressure sometimes remaining unchanged and sometimes falling precipitately with symptoms of hypotension The average pulse-rate rose after injection of hexamethonium, but in some patients either no change or a decrease was observed

Both the G F R and R P F usually decreased after the injection of hexamethonium In patients in whom the blood pressure fell considerably a substantial decrease in the G.F.R and R.P F was usually seen However, even when the blood-pressure was only slightly decreased, considerable alterations in the G F.R and R P F were observed in some patients The greatest change seen was immediately after injection Towards the end of the observation periods both the G.F.R. and R P.F. tended to rise—the R P F. more rapidly than the G.F.R This was reflected in the filtration fraction which tended to decrease during the period of recovery of G.F.R and R.P F.

After the injection of hexamethonium the average R V R rose initially but it diminished towards the end of the period of observation In some patients the more rapid recovery of the R P.F following the initial decrease resulted in the R V R falling below control levels, while the blood-pressure remained low; in others recovery was less rapid and the R V.R remained high

After injection of hexamethonium the average rate of urine flow fell progressively from the control levels, a greater fall being observed when the blood-pressure fell considerably At the same time the excretion of urinary sodium decreased, tending to parallel the rate of the urine flow The urinary excretion of potassium decreased immediately after injection but increased towards control values at the end of observation

In the five patients treated with reserpine the average blood-pressure before treatment was 218/121 mm Hg and during treatment 202/109. The pulse-rates were slower during treatment with reserpine, being 74 before treatment and 62 after treatment No great differences were noted in the G F R R P.F, or filtration fractions before or during treatment The R V R averaged 0 305 before treatment and 0 278 during treatment with reserpine reflecting the slight fall in the arterial blood-pressure

After the injection of hexamethonium in these five patients the alterations in renal hæmodynamics and in the excretion of water and electrolytes resembled those observed before treatment with reserpine Quantitative differences were, however, noted in some patients

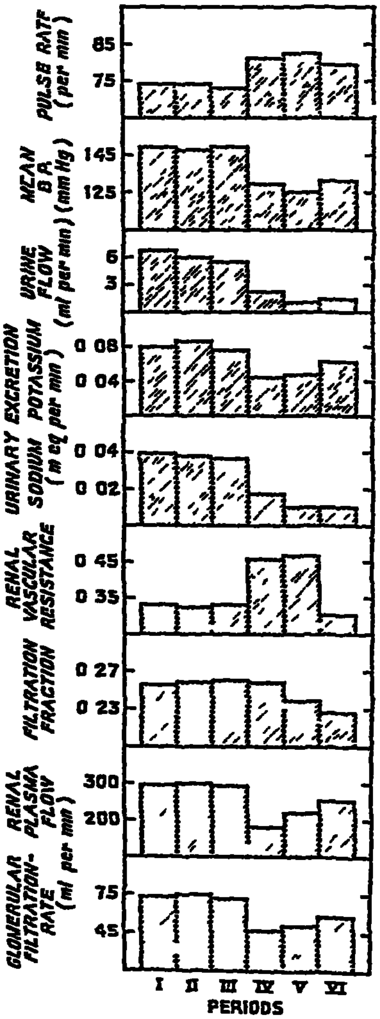

Fig 1—Changes induced by intravenous injection of hexamethonium bromide in 13 hypertensives Values are means of 13 patients Periods I–III are control observations and periods IV–VI those after injection

Discussion

These results confirm the observations that the injection of hexamethonium in hypertensive people tempor-

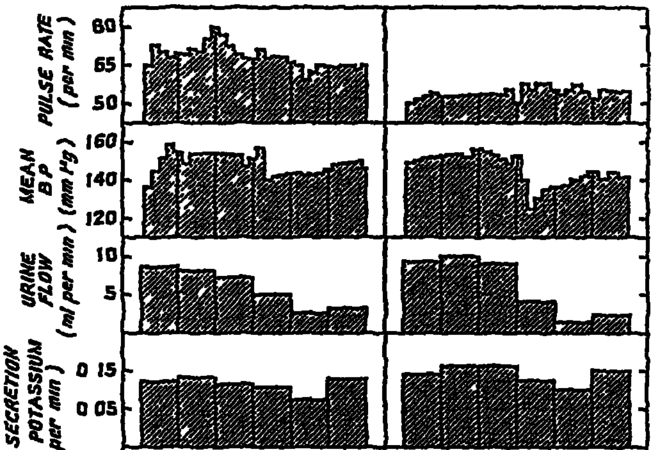

Fig 2—Case 10 effect of intravenous hexamethonium bromide before (A) and during (B) treatment with reserpine Hexamethonium injected at beginning of period IV.

arily alters the renal hæmodynamics and the excretion of water and electrolytes Freis et al (1953) did not observe alterations in the renal circulation when the injection of hexamethonium produced no fall in the blood pressure, but Mackinnon (1952), using pentamethonium, noted changes even when the blood-pressure did not fall In the present series minor alterations in blood pressure were sometimes accompanied by considerable alterations in the R P F and G F R Hexamethonium causes peripheral vasodilatation with increased blood flow to the extremities (Freis et al 1953), this may lead to the borrowing of blood from other parts of the body, including the kidneys, with a consequent reduction in blood-flow through these structures without any change in the systemic blood-pressure

Hexamethonium may either increase or decrease the R V R at the height of its action, judged by the blood-pressure (Mills and Moyer 1953) Both responses were observed in this series The result may depend on the ability and rapidity with which the renal circulation adjusts itself to sudden changes in blood-pressure In patients in whom the renal blood flow rapidly recovered while the blood pressure was low the R V R decreased below control values When the R B F recovered more slowly while the blood-pressure was rising, the R V R was increased *at the time of the peak action of the hexamethonium* In the two patients in whom the R V R was decreased renal function was good, judged by ordinary clinical tests In all the patients with impaired renal function R V R increased The severity of the disease, as it affects the *renal vasculature*, may determine the type of response

Mills and Moyer (1953) suggested that the increase in R V R may be explained on the basis of reflex vasoconstriction in response to the fall in blood pressure, *and that this is mediated via the* sympathetic nervous system through incompletely blocked ganglia On the other hand, the R V R is expressed as the ratio of the M B P to R B F, and the vasoconstriction inferred from this measurement may be the result of a shift of blood away from the renal circulation, together with a decrease in both the cardiac output (Werko et al 1951, Freis et al 1953) and *the* blood-pressure, and *consequent* arteriolar constriction

The effect of reserpine may take days or weeks to become apparent In this series 2 weeks' treatment was allowed before the second test, and a decrease in the *pulse rate* was *taken to indicate that* the reserpine was acting Moyer (1954) found no effect on the G F R and R P F in eight hypertensives during treatment with oral reserpine for 3 or more months In the five patients studied in this series the levels of G F R and R P F were similar before and after 2 weeks' treatment with reserpine The R V R was slightly less during treatment with hexamethonium in four of these patients owing to a slight fall in the blood pressure The pattern of response to hexamethonium before and during treatment did not differ Quantitative differences, however, were observed in some patients Case 11 developed hypotensive symptoms during the first examination, and the alteration in the renal circulation were more pronounced during this test than on the second occasion On the afternoon after the first examination the patient became pyrexial owing to an infection in a submaxillary salivary gland *from an impacted calculus* This could explain the differences observed It was found also that the effect of equal doses of hexamethonium in the same patient varied at different times Sometimes a test dose which had produced considerable changes in the blood pressure caused *only a slight* effect *during* the investigation Sometimes the opposite happened Familiarity with the procedure and small differences in technique may have affected the state of the patients and could explain the variations found These factors must be considered in interpreting the results

Parenteral hexamethonium decreases the rate of urine flow and the excretion of urinary sodium Though the fall in G F R may explain this in part, the fact that it persisted even when the G F R was again rising suggests increased *tubular reabsorption* of water and sodium as another factor The mechanism of this retention of sodium and water is unknown Preliminary treatment with reserpine did not alter the pattern of response as regards the rate of urine flow and the excretion of sodium and potassium except in one case in which no obvious reason for the difference was apparent

Summary

In thirteen patients with hypertension the effects of *intravenous hexamethonium on the renal circulation* and on the excretion of water and electrolytes were studied and in five of these patients examinations were repeated under treatment with reserpine

The effects of hexamethonium on renal hæmodynamics have *been confirmed—namely*, temporary decreases in glomerular filtration rate and renal plasma flow, usually an increase in renal vascular resistance, and a decrease in the rate of urine flow and in urinary excretion of sodium

Preliminary treatment with reserpine did *not* affect the changes produced by intravenous hexamethonium on the renal circulation

I am indebted to the medical committee of the Institute of Clinical Research, the Middlesex Hospital, for providing the facilities for this work In particular I thank Dr A Willcox, in whose unit it was done, for his constant encouragement and advice, and Prof A Kekwick, director of the institute

RENAL HÆMODYNAMIC EFFECTS OF HYPOTENSIVE DRUGS

II EFFECTS OF ORAL MAINTENANCE THERAPY WITH PENTAPYRROLIDINIUM BITARTRATE AND RESERPINE

LAWSON McDONALD

M.A., M D Camb, M R C P

ASSISTANT DIRECTOR, INSTITUTE OF CARDIOLOGY, UNIVERSITY OF LONDON, HONORARY ASSISTANT PHYSICIAN, NATIONAL HEART HOSPITAL, LONDON

LEVERHULME RESEARCH SCHOLAR

From the Institute of Clinical Research and Experimental Medicine, and the Department of Cardiology, Middlesex Hospital, London, and the Institute of Cardiology, National Heart Hospital

IN most hypertensive patients the systemic blood-pressure is lowered by adequate therapy with hypotensive drugs, and in some of them there is clinical evidence of arrest or regression of vascular disease The fall in blood-pressure must be accompanied by either a decrease in the total peripheral resistance or a fall in cardiac output, or both Such a readjustment of the circulation may lead to inadequate blood-flow through the essential circulations of the kidney, heart, or brain

The present study was designed to measure any change in the renal hæmodynamic pattern of patients with severe hypertension in whom a satisfactory clinical response to hypotensive therapy had been obtained The renal and vascular effects of continuous oral hypotensive therapy with reserpine ('Serpasil') and the ganglion-blocking agent pentapyrrolidinium bitartrate ('Ansolysen') are reported Parenteral administration of another ganglion blocking agent (hexamethonium bromide) causes a striking temporary alteration in the renal hæmodynamic pattern, which is unaltered by previously administered reserpine (Goldberg 1957)

Material and Methods

Of a larger series of patients receiving hypotensive therapy for severe sustained systemic hypertension, six were studied (four women and two men, aged 52–62) Case 7 had malignant hypertension, the remainder had severe hypertension, which was considered to be essential and which was associated with impairment of cardiac renal, and retinal function in varying degrees in the different patients, none of whom was in cardiac failure at the time of study In all the patients the systolic blood pressure before treatment was at least 210 mm Hg, and the diastolic at least 110 mm

The patients were admitted to hospital for an initial period of rest, during which no specific hypotensive therapy was given, and were observed until their blood-pressures became stable Renal plasma flows and glomerular filtration-rates were respectively measured by the *p* aminohippurate and inulin methods, as previously described (Goldberg 1957) The results reported are the averages of three periods each of about 15 minutes Hæmatocrits were recorded, and the renal blood-flow, filtration fraction, and renal vascular resistance calculated Cardiac outputs were determined by a dye dilution method using 'T 1824' and a photo-electric ear densitometer (Milnor et al 1953) All measurements were made with the patients recumbent

Hypotensive therapy with reserpine and pentapyrrolidinium was then started When a satisfactory sustained therapeutic effect had been obtained, and an adequate maintenance dose of the drugs established, the above tests were repeated The dose of pentapyrrolidinium varied in different patients and the second examination was made after periods of treatment varying from 17 to 80 days, these were kept as short as possible, so that progressive deterioration of renal function, due to the disease itself, would be unlikely to affect the results

Results

The results are shown in the accompanying table

Blood-pressure and Pulse-rate—The blood-pressure was lowered before and during the second study in all but one patient (case 18), in whom the pressure was temporarily raised to former levels at the actual time of the second study, although before it there had been good control In all patients except one (case 7) the pulse-rate was slower after treatment than before

Glomerular Filtration-rate (G.F R)—The average G F.R in the six patients was 70 ml per minute before treatment and 64 ml during treatment There was no marked change in G F R in any patient, in the five patients in whom the blood-pressure was reduced at the time of the second study the G F.R was slightly lower than before, and in the remaining patient (case 18) it was slightly higher

Renal Plasma Flow (R P F)—There was no significant change in R P F in the six patients before and during treatment, the average was 254 ml per minute before treatment and 256 ml during treatment

Filtration Fraction (F.F)—The average F F in the six patients was 0 279 before treatment and 0 253 during treatment The slight decrease reflected the lower G F R which usually occurred with treatment

Renal Vascular Resistance (R V R)—In the six patients the R V R averaged 0 400 before treatment and 0 309

EFFECTS OF MAINTENANCE TREATMENT WITH PENTAPYRROLIDINIUM BITARTRATE AND RESERPINE ON RENAL FUNCTION IN HYPERTENSIVE PATIENTS

A before treatment
B after treatment
B P blood pressure in mm. Hg The figures are averages for numerous observations at the time of each study
G F R glomerular filtration rate (ml. per min.)
R P F renal plasma flow (ml per min.)
F F filtration fraction
R V R renal vascular resistance

during treatment The decrease was due to the fall of blood-pressure

Cardiac Output—No uniform response as regards cardiac output was found in this small number of patients Some showed an increase in cardiac output and others a decrease

Discussion

The effects on renal function of a combination of drugs, the ganglion blocking agent pentapyrrolidinium bitartrate and reserpine, commonly used in hypotensive therapy, have been studied No marked alteration in the renal hæmodynamic pattern was found with maintenance oral therapy except a decrease of the R V R Ford et al (1953) observed the effects of maintenance therapy with oral hexamethonium in 13 hypertensive patients In the recumbent position no marked alterations in the G F R and R P F were observed, although there was a significant fall of the blood-pressure and a decreased R V R In 7 of their patients the effects of ambulation were studied before and during treatment, the postural reduction in G F R and R P F was somewhat greater during treatment than before

Oral reserpine was similarly found to produce no significant change in R P F (Moyer 1954, Andreae and Smith 1955) In the present study the combination of reserpine with another ganglion-blocking agent, pentapyrrolidinium, likewise did not alter the R P F, at least in the recumbent position The findings during treatment were similar to those found during the recovery phase following the injection of hexamethonium, with or without the previous administration of reserpine (Goldberg 1957) The renal circulation apparently adapts to the decrease in blood-pressure following maintained oral therapy with pentapyrrolidinium and reserpine, and maintains the renal blood flow

In the five patients in whom the blood-pressure was lower during the second study the G F R was then slightly less than before, and the F F was reduced During severe hypotensive episodes which can occur during treatment a more profound alteration in the renal hæmodynamic pattern is possible, but probably temporary Although the decrease in G F R was consistent, it is unlikely to be materially significant in these patients, because no evidence of progressive reduction in renal function was found with continued treatment Reduction in renal function, as judged by simple clinical tests, was exceptional in other patients who were treated with this combination of drugs and observed over long periods by one of us (L McD 1954, unpublished) When renal function did progressively deteriorate, there was evidence of critically impaired function before the start of treatment A small absolute decrease in the G F R in these patients could represent a considerable proportional reduction and be sufficient to aggravate existing renal insufficiency In this regard it was found that further deterioration tended to occur early in treatment, and was made manifest by a rising level of blood-urea (McDonald 1954 unpublished, Stover et al 1956) If this form of therapy is still indicated in patients with critically impaired renal function, it is our practice repeatedly to determine the level of the blood urea, particularly during the early stages of treatment

Hexamethonium given intravenously to hypertensive patients has been found to decrease cardiac output (Werko et al 1951, Freis et al 1953), to increase it in the presence of heart failure (Freis et al 1953), and to cause no significant change in cardiac output (Gilmore et al 1952) The present findings are inconclusive as regards the effect of oral pentapyrrolidinium and reserpine on cardiac output The changes observed differed in individual patients and, in view of the error of the method were of doubtful significance

During hypotensive therapy the possibility of interference with essential circulations exists It is concluded that optimal lowering of blood pressure, which is a criterion of successful hypotensive therapy, appears rarely to interfere significantly with renal function, and that simple clinical tests of renal function should detect such interference No evidence was found, in this small series, of a diminution in renal blood flow or of relative renal ischæmia, which might mitigate the advantages of hypotensive therapy

Summary

Renal plasma flow, glomerular filtration-rate, filtration fraction, renal vascular resistance, and cardiac output were measured in six patients with severe hypertension, before and during treatment with oral pentapyrrolidinium bitartrate and reserpine

Little alteration in the renal hæmodynamic pattern was observed, apart from a lowering of the renal vascular resistance

In patients in whom the blood pressure fell, the glomerular filtration rate and the filtration fraction were slightly reduced This is usually not of clinical significance, except in patients with critical impairment *of renal function before treatment, further deterioration* may then occur during treatment

Of the simple clinical tests of renal function, the blood-urea level especially appears to be a good guide *to the progress and management of such cases*

It is a pleasure to thank Prof Alan Kekwick, director of the Institute of Clinical Research, Middlesex Hospital, for encouragement and facilities for this work, the clinical research committee of the Institute for a grant *to one of us* (L McD), Dr T M Chalmers for helpful comment, and Dr Evan Bedford, Dr Walter Somerville, and Dr Arthur Willcox for encouragement and allowing us to study patients under their care

HYPERCALCÆMIA IN ACUTE LEUKÆMIA

C MAWDSLEY
M B Manc

R L HOLMAN
M B Leeds

CAPTAINS R A M C, QUEEN ALEXANDRA MILITARY HOSPITAL, LONDON

THE association of acute leukæmia and hypercalcæmia is rare and justifies record of the following case, in which many of the clinical features were attributable to the raised serum-calcium level

Case-report

In March, 1956, a soldier, aged 20, serving in Kenya, fell from a lorry and struck the left side of his chest For the next two weeks he had pain in the left lower chest, aggravated by movement and inspiration At the end of March he lost his appetite He was awakened on April 2 by epigastric pain and nausea, followed by repeated vomiting, which continued until admission to hospital in Nairobi two days later

On admission epigastric tenderness, a temperature of 101°F, and injection of his conjunctivæ were the only abnormal physical signs found Radiographs of his chest showed callus formed round the 7th left rib posteriorly Examination of his blood showed hæmoglobin 80% (11 8 g per 100 ml), white cells 8000 per c mm (neutrophils 31%, lymphocytes 59%, monocytes 1%, eosinophils 9%), and erythrocyte sedimentation rate 40 mm in the first hour (Wintrobe) A Mantoux test was positive 1/100 Widal agglutinations and culture of the blood were normal Routine testing and microscopy of the urine showed no abnormality

Progress

During the ensuing weeks the abdominal discomfort improved but the anorexia and vomiting continued The patient's temperature was often raised (99–102°F) in the evenings, and on April 16 he complained of aching pains in both hips and both knees

On May 22 evidence of renal damage was found the blood-urea level was 80 mg per 100 ml , and the highest specific gravity of the urine was 1 012 , and the urine often contained red and white cells and hyaline and granular casts Intravenous pyelography did not outline the kidneys Radiography showed rarefaction of the pelvic bones and femoral heads The hæmoglobin had decreased to 52% (7 7 g per 100 ml) The patient was given a blood-transfusion and flown home to hospital in England on May 26

Severe anorexia and vomiting, four or five times daily, continued , he complained of thirst and was passing an abnormally large volume of urine His obvious loss of weight, pallor, and injected conjunctivæ were the only abnormalities found on physical examination No enlargement of lymph nodes, liver, or spleen was detected Eye changes were a feature throughout the illness leashes of injected vessels ran from the cornea to the canthi , near the limbus, along the course of these vessels, were several small yellowish plaques which did not stain with fluorescein, but otherwise the picture was similar to phlyctenular conjunctivitis

Further investigations showed Hb 62% (9 3 g per 100 ml), white cells 2500 per c mm. (neutrophils 11%, lymphoctyes 63%, monocytes 5%, myelocytes 1%, primitive cells of uncertain type 20%), platelets 45,000 per c.mm An occasional normoblast was present A similar blood picture was found on repeated examinations over a period of weeks Bone marrow was difficult to obtain, aspiration being attempted from several sites, but satisfactory smears were made which showed sheets of primitive cells of lymphoid type Repeated examinations of the serum proteins, including paper electrophoresis, showed no abnormality, nor was Bence-Jones protein ever demonstrated in the urine The serum calcium level was consistently raised on many estimations, being 17–24 mg per 100 ml The levels of inorganic phosphate and alkaline phosphatase in the serum were always within normal limits The blood-urea level was raised, being 57–74 mg per 100 ml. The daily output of urine was about 3 litres of sp gr 1 010 Albumin, cells, and casts were constant findings The urinary excretion of calcium was 560 mg daily and of phosphate 1 2 g daily Radiographs showed widespread skeletal rarefaction, especially in the pelvis and femoral heads

Treatment

On June 15 the hæmoglobin had decreased to 36% (5 3 g per 100 ml), and the patient was started on a course of cortisone 300 mg daily and given repeated blood transfusions During the next few weeks he improved steadily His appetite recovered, vomiting ceased, and he gained weight and was able to get out of bed The biochemical picture also changed The serum calcium was within normal limits on several occasions The level of alkaline phosphatase in the serum rose to 21 K.-A units, and the excretion of calcium and phosphate, although still abundant, became much less The hæmoglobin increased to 13 g per 100 ml , but the white cells were still only 1500–2000 per c mm , and " blasts " were still present in the blood film. Platelets remained constant at about 40,000 per c mm There was no radiologically demonstrable change in the bones

Death

Towards the end of July the patient began to vomit again and to complain of anorexia and headache His hæmoglobin, despite transfusions decreased steadily, and the serum-calcium level was again high—15–16 mg per 100 ml On Aug 8 he developed widespread purpura vomited blood, and after three epileptic fits, became comatose and died

Necropsy Findings

Fourteen hours after death there were numerous petechial hæmorrhages in the skin and pericardium

Reticulo endothelial system —The bone marrow of the sternum femora, vertebræ, and ilium was replaced by red gelatinous material interspersed with many yellow areas Microscopically the marrow showed replacement of normal hæmopoietic tissue by sheets of large immature round cells of uniform size with little cytoplasm and vesicular nuclei containing a nucleolus , these cells corresponded to the lymphoblasts seen in the marrow smears Lymph nodes in the para-aortic, mesenteric, and axillary groups were moderately enlarged, up to 2 cm. in diameter, and their cut surfaces appeared uniformly pink , microscopically the normal architecture was lost, with an increase of large lymphoblasts Subcapsular and medullary sinuses were dilated and contained many large macrophages The spleen (440 g) had a normal cut surface and microscopical architecture but contained much iron pigment The liver (2060 g) had a normal cut surface, and microscopically showed infiltration of large lymphocytes in the portal tracts

Urogenital system —The kidneys (right 200 g , left 220 g) showed pale cut surfaces with a narrow cortex , wedge shaped nodules of infiltration involved both cortex and medulla Microscopically the nodules consisted of large uniform round cells similar to those seen in the marrow , there were numerous deposits of calcium in the cortex and medulla, but the glomeruli showed little change

Endocrine system —The parathyroid glands were of normal size and structure

The brain showed focal cortical hæmorrhages, especially in the frontal and temporal cerebral lobes

Discussion

This case of acute lymphoblastic leukæmia of the " aleukæmic " type presented unusual features Rarefaction of bones and severe hypercalcæmia, accompanied by anorexia, abdominal pain, and vomiting, with polydipsia and polyuria, may occur in hyperparathyroidism (Snapper 1952) Sarcoidosis too may present with similar clinical features and a high serum-calcium level (Dent et al 1953, McSwiney and Mills 1956) Myers (1956), reviewing 61 cases with hypercalcæmia, noted 1 case of acute leukæmia with a serum calcium level of 11 8 mg per 100 ml , and in a case of lymphosarcoma he found a serum calcium level of 20 4 mg per 100 ml. We have found no other record of hypercalcæmia in leukæmia nor any description of leukæmia presenting a clinical picture like that in the present case

Leukæmia has long been known to cause bony abnormalities Erb (1934) described rarefaction as one of the changes in the bones of children with acute leukæmia Kalayjian et al (1946) reviewed 144 cases of leukæmia with radiological evidence of bone involvement and found that 96% were of lymphoid type In a recent survey Griffiths (1955) has emphasised the association of bone changes with the " aleukæmic " forms of acute leukæmia in children

Hypercalcæmia, usually of moderate degree, may occur in any case of neoplastic invasion of bone—e g , by metastatic carcinoma and by myeloma Absence of new bone formation and the consequent normal level of alkaline phosphatase in the serum are features of myelomatous invasion (Snapper 1952)

In the absence of any detectable change in the serum-proteins we considered two possible explanations of the high blood calcium level and rarefaction of the bones in the present case hyperparathyroidism and invasion of bone by leukæmic tissue The remote possibility of a coincidental primary hyperparathyroidism was considered, but the alkaline phosphatase level was normal and at necropsy the parathyroid glands were normal There was considerable damage to the kidneys in the present case from leukæmic infiltration of the kidneys and, later, presumably from nephrocalcinosis Parathyroid overactivity secondary to renal failure may give rise to hypercalcæmia, but in the present case the normal alkaline phosphatase level and the lowered serum-calcium level after treatment with cortisone are points against this explanation

We suggest that the likely cause of the hypercalcæmia was continued and widespread leukæmic invasion of bones Temporary remissions of acute lymphoblastic leukæmia after cortisone therapy are known (Wilkinson 1953) Such a remission took place in the present case and was reflected by a fall in the serum-calcium level and a rise in the serum alkaline-phosphatase level, presumably owing to cessation of bone destruction with some attempt at new bone formation A similar sequence of events occurred in a case of lymphosarcoma treated with nitrogen mustard and cortisone (Myers 1956) and in cases of sarcoidosis treated with cortisone (Dent et al 1953) Some regression in the bony changes, shown radiologically, was noted by Dresner (1950) after the treatment of cases of acute leukæmia with aminopterin

The chronic symptomless conjunctivitis was an interesting feature for which we can offer no satisfactory explanation, post-mortem section of the eyes not being permitted Leukæmic deposits in the conjunctivæ have been described (Wintrobe and Mitchell 1940), but the descriptions do not seem to fit the changes in the present cases

Summary

In a case of acute lymphoblastic leukæmia, hypercalcæmia was probably due to invasion of bones by leukæmic tissue

We are grateful to Lieut Colonel J A G Carmichael, R A M C, physician in charge of the patient, and Lieut-Colonel P D Stewart, R A M C, for advice, and the technical staff of Eastern Command laboratory for help with the investigations

Preliminary Communication

ALLOXAN AS A POSSIBLE THERAPEUTIC AGENT FOR PRIMARY CARCINOMA OF THE LIVER

With illustrations on plate

The relationship of endocrine action to the genesis and therapy of advanced cancer has received considerable attention in recent years, and especially during the past year[1 2] This approach may yet prove of value in elucidating host tumour relations and tumorigenesis

In the experimental field there is evidence that the production of alloxan diabetes in rats almost entirely prevents the induction of hepatomas by feeding azo-dyes,[3] and inhibits tumour growth or reduces the mortality rate in rats receiving implants of carcinoma (but not sarcoma)[4] More recently Ingle[5] has reported that diabetes induced in rats by partial pancreatectomy suppressed tumour growth

Hepatocellular carcinoma in man is invariably fatal, usually 4–6 weeks after clinical diagnosis[6] No form of therapy has hitherto been found to be of any value, even in prolonging life

Bearing all these experimental and clinical data in mind and despite the fact that alloxan had not, to our knowledge previously been given to man we considered it worth while to study the effects of alloxan on patients with primary hepatic carcinoma Diabetes, if induced, would be controllable with insulin

CLINICAL TRIAL

The preliminary results in three hopelessly advanced cases (for example see fig 1) and one with a slowly growing tumour, studied over the past year, are reported here The diagnosis of primary hepatic carcinoma was proved in all four cases by needle biopsy of the liver

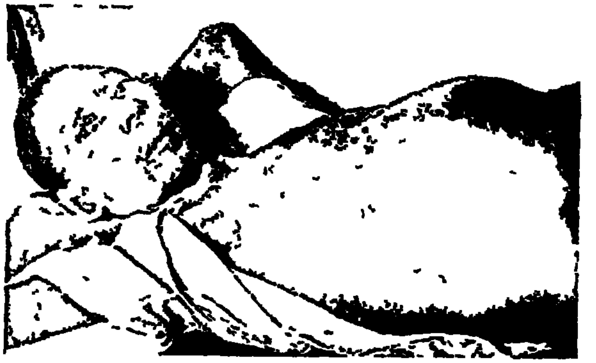

Fig 1—Case 2 immediately after paracentesis, showing bulging nodular liver

Alloxan 70–150 mg per kg body weight was administered intravenously, over a period not exceeding one minute, as a fresh 20% solution of alloxan monohydrate in distilled water These doses are known to be diabetogenic for most animals There was no significant untoward reaction to any of the seven injections given to our patients

Cases 1 and 2, African males aged 48 and 40, with typical, rapidly growing, and metastasising cancers, each received two injections of alloxan (case 1 at 16 day and case 2 at 58 day intervals), and lived for 18 and 103 days, respectively, after the first injection Case 3, an African male aged 56, was moribund before receiving a single alloxan injection He died within a few days, no post mortem being obtained, death could not be attributed to the treatment Case 4, an African female aged 28, with a slowly growing cholangiocellular carcinoma, has had two injections of alloxan and is still in hospital with no deterioration in her clinical condition

After the first alloxan injection case 1 experienced dramatic cessation of pain, which did not return In cases 1, 2, and 4 the liver became slightly but measurably smaller The fasting blood sugar levels in cases 1 and 2 initially rather low, showed slight transient rises after alloxan but always remained well within normal limits Glucose tolerance tests, before and after alloxanisation in these cases, showed no significant changes Case 4 had normal resting blood-sugar levels at all times, but her glucose tolerance tests, before and after alloxan, showed lag storage, which seemed slightly greater on the latter occasion *Assessment of therapy in this case* will be difficult because of the longer history and the quite different type of cancer

Histological study of necropsy material, obtained from cases 1 and 2 only, revealed extensive necrosis of primary and secondary tumours *Unusually marked sclerosis* was present both in the primary and in *all* secondary tumours in case 2 (figs 2 and 3) Since necrosis of hepatic carcinomas often develops spontaneously,[6] this may not be significant However, the extent of the necrosis, and especially of the tumour sclerosis in case 2, may merit special emphasis Also of interest was the absence of any histological evidence of damage to either pancreatic islets or kidneys in the one case studied

CONCLUSIONS

We consider the following findings *to be of some interest and perhaps attributable to the treatment* (1) the cessation of pain in case 1, (2) the reduction in size of the liver in cases 1, 2, and 4, (3) the extensive sclerosis in both primary and secondary tumours especially in case 2, particularly (4) the unusually long survival of case 2 (with a rapidly growing hepatocellular

[6] Berman C Primary Carcinoma of the Liver London 1951

carcinoma) for more than 5 months after the onset of symptoms (Berman[6] found that " the duration [of primary carcinoma of the liver] was never more than 4 months from the first appearance of symptoms "), and (5) the absence of hyperglycæmia and glycosuria after alloxanisation—noteworthy especially because decreased glycosuria has been reported in human diabetics developing certain tumours[7] and in diabetic rats bearing tumour transplants[5] Moreover, alloxanised rats bearing tumours have lower blood-sugar levels than alloxanised tumour-free controls[4]

In the light of these findings we consider that the alloxan therapy *may* have had some effects in two of the cases, and *may* perhaps have prolonged the life of case 2

The primary object of this note is to arouse interest in the possibility of treating with alloxan primary carcinoma of the liver, and possibly advanced carcinomas arising in other sites Our findings provide some basis for recommending further and more extensive investigation of the significance and interactions of alloxan injections on cancers, as well as of the abnormal carbohydrate metabolism occurring spontaneously in association with cancers[8] However, at the present time, we do not feel justified in making *any* special claims for this form of treatment

Since the above was written, three further cases of primary carcinoma of the liver have been given 1 injection each of alloxan (100 mg per kg body-weight) On the day following his injection, the third patient developed total anuria lasting 4 days, confirming the potentially nephrotoxic action of alloxan already described in animals

Our thanks are due to Dr. S Disler, hospital superintendent for permission to publish our findings, to Dr R Pooler and Dr F J Davidson for clinical material, to Prof I Gordon and Dr J Wainwright for necropsy findings to Dr M W Susser, Dr Z A Stein, and Dr L S Lange for clinical assistance, and to Prof J Maisin for encouraging us to make this preliminary report

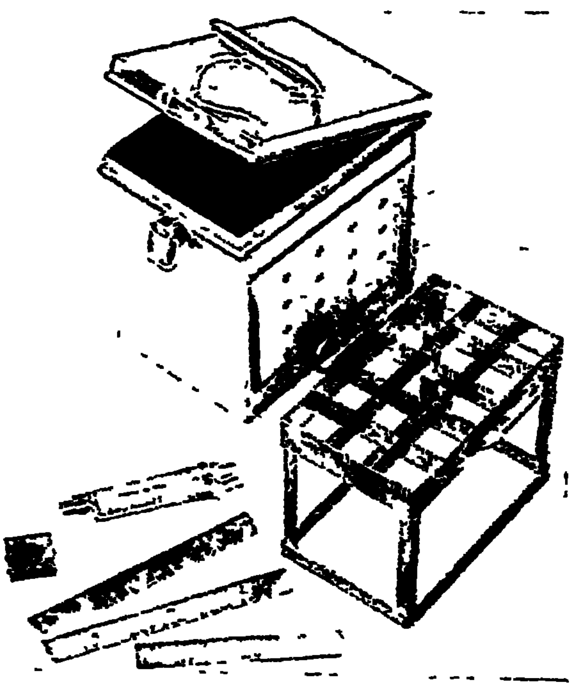
New Inventions

ST JOHN'S HOSPITAL SYRINGE CARRIER

A CENTRAL syringe-sterilising service is essential to all hospitals but it involves much time-consuming labour in the wrapping of individual syringe pistons, barrels, and needles The materials involved—polyethylene, glass metal, and specially tailored cotton containers—are all expensive

The container illustrated here has been designed to solve these problems so far as the anæsthetist is concerned It consists of a box measuring $7\frac{1}{2} \times 5 \times 7\frac{1}{2}$ in and containing a frame holder designed to take 14 assorted syringes and 15 needles By manipulation of the central bars the contents can be varied to suit an individual operating-list and combinations of syringes varying from 2 ml to 20 ml in capacity can be arranged for sterilising to suit individual requirements

All parts of this carrier are easily removable for cleaning It can be used in an autoclave or in a hot-air oven Its construction of heavy-gauge copper enables it to withstand heavy wear Cultures placed inside an assembled syringe in the centre of the box and surrounded by a full complement of syringes have been rendered sterile in experimental tests



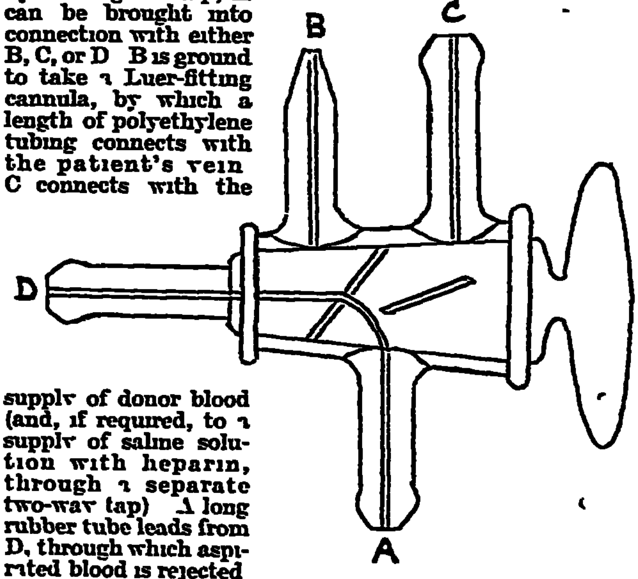
This instrument is made by Messrs W H Bailey & Son Ltd, London, S W 1

L H Lerman
M R C S, D.A.

St John's Hospital Lewisham

A THREE-WAY TAP FOR EXCHANGE TRANSFUSION

THE design of the tap, which is made of glass, is apparent from the accompanying figure A syringe is fitted to A by means of a short piece of rubber tubing by turning the tap, A can be brought into connection with either B, C, or D B is ground to take a Luer-fitting cannula, by which a length of polyethylene tubing connects with the patient's vein C connects with the supply of donor blood (and, if required, to a supply of saline solution with heparin, through a separate two-way tap) A long rubber tube leads from D, through which aspirated blood is rejected



The two parts of the tap are dry-sterilised separately and assembled after the surface of the tap has been lightly smeared with sterile lubricant—e g, soft paraffin

The advantages of this glass tap over metal taps with a similar purpose are lightness and ease of cleaning and of sterilisation It has been thoroughly tested in use over the past five years

The tap is made by Camlab Glass Ltd, 50a, Burleigh Street Cambridge

Reviews of Books

Diseases of the Breast

C D HAAGENSEN, M D , professor of clinical surgery, College of Physicians and Surgeons, Colombia University
Philadelphia and London W B Saunders 1956
Pp 751 112*s*

THIS is the most important book on diseases of the breast which has appeared for many years Dr Haagensen is well known for his contributions to our knowledge of the breast, and he has now distilled the wisdom from twenty-five years' concentration on the subject His data are the records, large in volume and perhaps unique in the detail with which they have been investigated, of the Colombia Presbyterian Center in New York over the past forty years Dr Purdy Stout has been the pathologist chiefly associated with Dr Haagensen, and his influence is as clear in the text as in the beautiful photomicrographs

Dr Haagensen's chapters on the complex which used to be called chronic mastitis are interesting and thought provoking, though not perhaps entirely in line with British thinking so far as epithelial proliferation is concerned His chapter on mammary duct ectasia is masterly, as one might expect from the man chiefly responsible for distinguishing this entity from chronic mastitis More than half the book is devoted to carcinoma The chapter on the choice of treatment contains a description of a method of trephine biopsy of lumbar vertebræ and its results, and it also discusses very fully the well known criteria of operability of Haagensen and Stout The sections on radiotherapy and hormone treatment are, as one might expect from a surgeon, shorter than the chapter on surgical treatment, in which Haagensen describes in detail the careful radical mastectomy on which he relies for the early case

This work is a personal statement by a man who has read widely and thought deeply and objectively about breast disease, and who is humble enough to include a section on personal diagnostic errors The book is well illustrated It will command attention from all who are interested in its subject

Human Perspiration

American Lecture Series YAS KUNO, M D , member of Japan Academy Springfield, Ill Charles C Thomas
Oxford Blackwell Scientific Publications 1956
Pp 416 72*s*

IT *is some twenty years since the author first* summarised contemporary knowledge of the physiology of perspiration In the present volume he presents the results of his lifelong study of the subject, making available data from much hitherto unpublished research carried out in his own laboratory The book will be read by physiologists, and its lessons should be assimilated by the thoughtful dermatologist and tropical practitioner , but it contains a wealth of information to interest the pediatrician and the student of electrolyte metabolism, as well as the neurologist and the surgeon concerned with the autonomic nervous system Above all, it provides the pleasure of following with the author the evolution of knowledge in a field that he has made peculiarly his own This is an exhilarating book

Schizophrenia 1677

A Psychiatric Study of an Illustrated Autobiographical Record of Demoniacal Possession IDA MACALPINE, M D , and RICHARD A HUNTER, M D M R C P , D P M London
William Dawson 1956 Pp 197 £6 10*s*

THIS beautifully produced volume gives a full account of the mental illness of an Austrian artist, Christoph Haizmann, in the year 1677

Haizmann thought that he had made a pact with the Devil and his illness broke out at the time when his agreement to sell himself to the Devil was due to take effect His mental distress was relieved by exorcism and by what he and the priests who succoured him held to be the intervention of the Blessed Virgin He then joined a religious order, and although tempted by apparitions of fiends managed to live fairly peacefully for another twenty three years

Haizmann left pictures of the Devil in the guises, all progressively more diabolic, in which he appeared to him on nine occasions, also of the miraculous worsting of the fiend by the Virgin These are reproduced in colour, and the original manuscript of Haizmann is given in photolithography

The body of the book is taken up by a full account of the painter's illness, and a discussion of this in relation to the development of Freud's theories regarding paranoia The authors' previous examination of psycho analytic thought, as exemplified in Freud's writings on the Schreber case, is here expanded

Head Injuries and Their Management

FRANCIS ASBURY ECHLIN, M D , C M , M SC , MED SCD , F A C S , professor of clinical neurosurgery, New York University—Postgraduate Medical School Philadelphia
J B Lippincott London Pitman Medical Publishing Co 1956 Pp 127 24s

THIS is a sound and practical account for general surgeons of the handling of head injuries The danger of transporting unconscious patients in the supine *position are, however, not emphasised , and the section* on reablement and post-traumatic epilepsy are disappointing in comparison with the excellence of the chapters on the acute stage

---

British Surgical Practice Surgical Progress 1956 (London Butterworth 1956 Pp 396 47*s* 6*d*) —The latest volume of this work, edited by Sir Ernest Rock Carling and Sir James Paterson Ross, follows the course of its predecessors Of the 11 original articles, all of them excellent, those by W J Sharrard on poliomyelitis, by D H Patey and A C Thackray on parotitis, and by F W Holdsworth on traumatic paraplegia seemed especially good There are five critical surveys, Hamilton Stewart's beautifully illustrated contribution on partial nephrectomy being outstanding The abstracts contain summaries of *150 important surgical papers* published mostly in 1955 and early 1956 The ' noter up ', (an ugly title for a valuable section) keys the new information to the parent volumes This is a useful book

Diagnostic Procedures for Virus and Rickettsial Diseases (2nd ed New York American Public Health Association 1956 Pp 578 $7 50) —Since the first edition of this book, edited by Prof Thomas Francis and Dr Joseph F Smadel, appeared in 1948 there have been important advances in the techniques of investigating viruses The second edition thus appears very different from the first and includes a great deal of new information on tissue culture techniques For anyone who is starting to do work with viruses and who would like authoritative information on how to handle them this is a most valuable book The treatment is very uneven, however, and there are some anomalies It is surprising that measles is dealt with in half a page, while inclusion blennorrhœa has eight pages The new adeno viruses are considered under primary atypical pneumonia, this is a doubly unfortunate chapter since it gives very little prominence to other diseases caused by adenoviruses, and it does not mention the recent work of Liu, Eaton, and Heyl on the virus which they recovered from cases of primary atypical pneumonia accompanied by an increase in cold hæmagglutinins *Finally, it is odd to see great stress laid on* the hæmagglutination test in the diagnosis of dengue while this valuable test is sadly neglected in the chapters dealing with other viruses of the same group—i e yellow fever and encephalitis viruses Nevertheless this book is likely to be in frequent use in many bacteriological laboratories

The Dental Treatment of Maxillo-Facial Injuries (2nd ed Oxford Blackwell Scientific Publications 1956 Pp 372 17*s* 6*d*) —When first published, this book brought together in a small space most of the current knowledge on its subject The second edition, edited by Sir William Kelsey Fry and Mr Terence Ward is basically the same book with the addition of a chapter on the use of antibiotics and a section on the use of alveolar wires Many of the elisions and errors of the first edition remain uncorrected and there is little reference to the vast increase in knowledge in the past *fourteen years* but the book is well laid out and the chapters on the general care of the patient, and particularly on feeding and on the use of antibiotics, are excellent

THE LANCET

LONDON SATURDAY, JAN 12, 1957

The Support of Medical Research

AN international symposium on the support of medical research met in London two years ago[1] under the chairmanship of Sir **HAROLD HIMSWORTH** and a report,[2] now published, represents the outcome of their deliberations Few will disagree with the opinions and advice set out therein, but agreed aims on the final common purpose of medical research are hard to translate into action when they involve nations so far apart on the economic scale as Yugoslavia and the United States In this respect the report is curiously detached the meeting seems to have recorded no dissenting voices It will be noted however, that many of the ideas expressed at the symposium were previously embodied in the white-paper on clinical research in the National Health Service[3], and the 81 articles to which the conference agreed suggest that the organisation of the Medical Research Council was accepted as a pattern Certainly, the aims and purposes these articles embody are closely related to our own situation

In Britain the State has become the great patron of research through, on the one hand, the University Grants Committee and the universities and, on the other, the Privy Council and the research councils For the tremendous work done by the M R C there can be little but admiration It finances projects beyond the purse of the university, it seeks out promising men for research careers, it supports and develops good research wherever it is perceived, and it undertakes large international responsibilities, such as keeping track of the influenza virus in the National Institute for Medical Research at Mill Hill Before we pass it on for export and emulation, however, we should consider a question that is often asked and is hard to answer with certainty does a large central institute, remote from medical schools and hospitals, drain away too much research and teaching talent from the universities? Perhaps the conference had qualms about this, for the report makes much of the traditional place of the universities in the expansion of knowledge, and it emphasises the importance to the investigator of teaching and other university contacts which often miraculously clarify his mind Thus it is considered vital that the investigators should continue to teach and inspire the young, and that research organised by a central body should be closely integrated with university work

The central body or research council has a heavy responsibility—for initiating research and for choosing and sometimes even discarding investigators (The minds of those who must make early choice of promising investigators can never be free from anxiety about the human difficulties that may arise when a research-worker of, say five years' standing has to seek ordinary professional work) Since the members of the M R C can hardly be expected to have supernatural powers of judgment, occasional errors are possible at all their levels of function, and it is therefore essential that the universities, with the help of patrons and private benefactors, should also be in a position to reach an independent evaluation of research, supporting it if necessary out of local endowment funds There are indeed risks in too much government aid for medical research—for example, it could degenerate into applied research for the Services, or it could be subject to political control and interference Though the M R C and the profession are very much on their guard against such abuses in this country, others may be less favourably placed Moreover, as Sir **ERIC ASHBY**[4] has explained, the patronage of private wealth is still important in maintaining academic freedom In these days the private patrons are often big business firms, and the help which some of these have given both at home and abroad, has been as enlightened as it is generous **ASHBY** pointed out, too, that the universities are not always staffed by research geniuses in every department first-rate administrators enthusiastic teachers, and good reviewers and organisers are all needed Because it is in a position to make far wider use of talent of all kinds, a university can maintain a flexibility denied to a body concerned only with research When the head of a department has research talent, the university should be able to provide on his staff the administrative and teaching assistance needed to keep the balance, and vice versa The report of the symposium recognises fully that the universities provide the intellectual climate, best suited for research development and that it is with their work that the activities of the central research body should be most closely integrated

If the universities accept this policy, some further hard spade-work, at both the preclinical and clinical levels, will lie ahead before all the fruits can be harvested The symposium noted with regret the falling recruitment of medically qualified men and women to the preclinical sciences, but it did not mention the gross differences in salary which are largely responsible—and which must be corrected before the situation can really improve If Northern Ireland can give its preclinical teachers distinction awards, it should not be impossible to ensure corresponding recognition of merit on this side of the Irish Sea At the clinical end of medicine there are also obstacles still to be overcome While the university clinical unit is strongly established in the Scottish schools and is expanding into almost all the provincial medical schools, the University of London has recently lost a professorial unit, and six of its twelve undergraduate schools have never had one Whatever the merits and demerits of such units as a means of teaching, they have certainly become the focusing points for the development of clinical research It is unfortunately obvious that the existing London units cannot absorb all the gifted and energetic young men seeking facilities for investigation Without more academic bridgeheads into the clinical field the best-laid plans for research can come to nothing The M R C lacks the powers to create these bridgeheads, and the task has to be faced by the university, where it is capable of taking the initiative If the universities wish to accept the proffered support for clinical research, they must make their own contribution in improving the organisation of university medicine The need is urgent, since already a generation of young and promising workers in medicine are beginning to feel that their training and talents are not appreciated Their enthusiasm can wither into cynicism, and we are in danger of either wasting their genius or allowing it to trickle away overseas

Some non-teaching hospitals with whole-time staff are now winning a higher reputation for research and quality of service (which go hand in hand) than the older teaching centres Such competition is healthy, but some teaching hospitals lock as though they are failing to rise to the challenge Unless they can read the writing on the wall, they will face slow decay The teaching centres, in particular, while avoiding self-satisfaction, must accept the tasks of leadership with all the support which can be theirs for the asking If the recommendations of this report are accepted as a policy to be pursued by the M R C, our universities must make equal efforts to ensure that the plan will work

Hypotensive Drugs and Renal Function

IN the armoury of modern therapeutic weapons there are few with so wide a popularity as the drugs which reduce blood-pressure, and there can surely be no other treatment in which the target is so blurred, the aim so erratic, and the motive power so uncertain How many patients receive homœopathic doses which have negligible effect on the blood-pressure? How many whose blood-pressure is effectively reduced have on that account a longer expectation of life, a greater freedom from complications, or even a relative relief from incapacitating symptoms? In how many do sudden or serious accidents follow lowering of the blood-pressure? On what criteria are we to select patients for treatment and what are the contra-indications? Nearly ten years after the introduction of the hypotensive drugs, there are, for the large majority of patients treated, still no clear answers

In this issue we publish three articles from two groups of investigators who have been studying the effect of hypotensive drugs on renal function Many patients with high blood-pressure are suffering from primary renal disease or from essential hypertension with renal involvement—so called malignant hypertension Since the prognosis is serious, there is a natural inclination to try any treatment that might help, so it is important to know whether renal function can really be improved by lowering the blood-pressure, or whether there is, in fact, a danger of impairing it further High blood-pressure may worsen the prognosis in renal disease in a variety of ways it may produce heart-failure, which in turn depresses renal function, it may give rise to cerebral complications, such as hæmorrhage or thrombosis, or more rarely to reversible attacks of hypertensive encephalopathy, it may lead to impairment of vision due to retinal hæmorrhages, or, more seriously, the malignant form of hypertension with papillœdema may ensue All these complications are commoner in renal than in essential hypertension Apart from extrarenal complications, there is good evidence, as the experiments of WILSON and BYROM[1,2] and of FLOYER[3] have shown in animals, that hypertension of sufficient degree produces renal vascular damage which may seriously affect prognosis There are thus ample reasons for attempting to lower the blood-pressure in patients with hypertension of renal origin But it is important to know whether it is safe to do so in the presence of impaired renal function, whether renal failure may be precipitated, and, on the positive side, whether the natural course of the disease may be prolonged by protecting the kidney from hypertensive vascular damage

Occasionally idiosyncrasy to ganglion-blocking agents or excessive dosage may cause severe hypotension As in circulatory shock, anuria may result[4] and it is then an urgent matter to raise the blood pressure—for example, by methedrine or adrenaline injections Apart from this mishap, which is usually avoidable, the healthy kidney possesses an effective mechanism for maintaining its circulation in the face of wide variations in systemic blood-pressure A temporary reduction in glomerular filtration rate (G F R) and renal plasma flow (R P F) and an increase in renal vascular resistance (R V R) usually follow the administration of ganglion-blocking drugs, and may *be observed even when the blood-pressure does not* change[5] Dr GOLDBERG reports on p 74 that the effect of hexamethonium on R V R depends on the initial *state of renal function, impaired function being* associated with increased R V R MOYER[6] found that in hypertensive patients reserpine did not affect G F R and R P F GOLDBERG adds that preliminary treatment with reserpine does not alter the effects of hexamethonium on renal circulation Apresoline differs from the other hypotensive drugs in producing an increase in renal blood-flow[5] These observations on the "acute" effects of the hypotensive drugs do not seem to be of much immediate value in predicting the results of treatment, particularly if renal function is impaired Apresoline should be the drug of choice, since an increase in R P F might be expected to improve kidney function Unfortunately it has proved disappointing in the treatment of patients with renal hypertension On another page Dr MCDONALD and Dr GOLDBERG report that, in essential hypertension maintenance therapy with oral pentapyrolidinium bitartrate ('Ansolysen') and reserpine produces no diminution in renal blood-flow or other evidence of renal ischæmia, and they conclude that in patients with initial renal impairment simple clinical tests of renal function, especially the blood-urea level, are an adequate guide to progress

Dr ABRAHAMS and Professor WILSON describe the effects of ganglion-blocking agents, with or without reserpine, in patients with varying degrees of renal impairment due to primary renal disease or malignant hypertension Repeated measurements of blood urea urinary urea concentration, and creatinine clearance were made during short treatment for two to four weeks and during maintenance therapy continued for up to two years Satisfactory reduction of blood

6 Moyer J H *Ann N Y Acad Sci* 1954 59 82

pressure did not lead to further deterioration of renal function unless considerable impairment was initially present—i e , blood-urea over 70 mg per 100 ml and creatinine clearance less than 30% They emphasise, however, the need for accurate diagnosis of the underlying renal disease , for reduction in blood-pressure is more likely to precipitate uræmia than in patients with a progressive active nephritis (e g chronic type-II nephritis) in patients with a relatively inactive inflammatory lesion, such as chronic type-I nephritis or chronic pyelonephritis, in which hypertensive renal damage is now thought to be the dominant cause of renal failure ABRAHAMS and WILSON point out that in many patients with chronic renal disease the sudden deterioration of renal function in the late stages is preceded by a relatively abrupt rise in blood-pressure If therapy is introduced at this point and the hypertension is well controlled, there is evidence that the onset of renal failure may be delayed In those patients who persevered with treatment, the malignant form of hypertension so common in renal disease, was not observed These clinical results lend support to the conclusions derived from experimental studies in animals—namely, that, in certain forms of chronic renal disease, hypertension leads to renal vascular damage and accelerates renal failure Nevertheless, when renal disease has progressed to the stage of nitrogen retention, hypotensive therapy can lead to only a limited increase in the expectation of life—a few years at the most As in essential hypertension cerebral vascular accidents remain a major hazard

Vancomycin

THE present-day pharmaceutical equivalent of the Gold Rush is the intensive and systematic screening of soil samples for new antibiotics Thousands of soil samples are being collected by amateur and professional mycologists all over the world, and submitted to various industrial and university laboratories Aqueous extracts are prepared and analysed for their microbe content, and these organisms are then screened for possible antibiotic activity Many samples may seem promising at first, but only a few satisfy the rigid criteria demanded for clinical trial To the investigators' chagrin, some promising antibiotics turn out to be identical with those already in clinical use , and others become discredited by their toxicity. Finally, one out of the thousands of soil samples survives the stiffest of hurdles clinical evaluation, and is acclaimed on an Olympic pedestal alongside its predecessors Various species of the genus streptomyces have so far produced streptomycin, chloramphenicol, neomycin, chlortetracycline (aureomycin), oxytetracycline (terramycin), nystatin, erythromycin, carbomycin, novobiocin, and oleandomycin

A recent addition is vancomycin, isolated from soil obtained in Borneo and India Although vancomycin-producing strains were subsequently found in soil from other parts of the world, including North America, the species has been designated *Streptomyces orientalis*[1] Vancomycin hydrochloride is a white solid very soluble in water, and relatively stable[2] It is bactericidal, and like that of penicillin, its principal action is against gram-positive bacteria, particularly when they are multiplying Organisms sensitive to it include pneumococci, streptococci staphylococci, and clostridia FAIRBROTHER and WILLIAMS[3] recently reported that in vitro, the gram-negative gonococcus was also highly susceptible The main indication for the use of vancomycin, however, is an infection due to strains of *Staphylococcus aureus* resistant to other antibiotics This usually implies a strain found in hospitals, where the wide use of antibiotics has encouraged the emergence of drug-resistant organisms It is fortunate that such strains are at present rarely encountered in infections outside hospitals, but how long they will remain thus confined no-one can say In-vitro sensitivity tests must be performed before the most potent antibiotic can be chosen to deal with a serious staphylococcal infection Until the results are available, the clinician must in an emergency decide which agent is most likely to be successful If the infection has been contracted outside a hospital penicillin will probably and tetracycline will almost certainly be effective On the other hand, *serious* infections contracted in hospital should be treated at the outset with an antibiotic which is in least current use in that particular hospital This will do much to ensure early control of the organism and may prevent an outbreak of cross-infection in the ward As we have often declared, the wisest course is to hold in reserve an antibiotic which will subdue staphylococci that are resistant to other forms of attack , erythromycin has been the one most often held back in this way and there have been signs that chloramphenicol was returning to popularity, despite its occasional association with blood disorders The introduction of other antistaphylococcal drugs including vancomycin novobiocin, and oleandomycin now permits a wider choice for the strategic reserve If the laboratory report subsequently shows that the reserved drug is not the only one to which the infecting organism is responsive then the erythromicin (or whichever drug it is) can go back into reserve The actual reserve drug for each hospital should be changed from time to time in the light of laboratory reports

Whereas novobiocin and oleandomycin are well absorbed from the intestine, vancomycin must be given intravenously to produce any action other than in the intestine After either oral or intravenous vancomycin, the fæces become odourless and strains of clostridium and *Streptococcus fæcalis* disappear or become much fewer but the gram-negative flora persists The persistence of the gram-negative organisms in the intestine should prevent the emergence of yeasts, and mucocutaneous moniliasis has not so far been reported after the administration of vancomycin When vancomycin is taken by mouth most of it is excreted in the fæces and only negligible amounts can be detected in the blood or urine After intravenous injection, it is rapidly excreted in high concentration by the kidneys As only small quantities reach the bile, it seems that vancomycin unlike many other antibiotics, is not concentrated and excreted by the biliary system It is detectable in pleural, pericardial, synovial, and ascitic fluids after intravenous injection It does not diffuse into spinal fluid which is not unexpected in view of the relatively large size of the vancomycin molecule The only toxic reactions observed by GERACI and his co-workers [2] at the Mayo Clinic were occasional rigors, erythematous or morbilliform rashes, and phlebitis at the site of repeated intravenous injections The dose of oral or intravenous vancomycin is 0 5 g six-hourly, continued for about one week, depending upon the severity of the infection and the response to treatment Such doses have produced good results by mouth in staphylococcal enterocolitis and intravenously in staphylococcal septicæmias and osteomyelitis

It remains to be seen whether vancomycin is best used alone or in combination with another antibiotic It is even more important for the community's sake to decide whether a combination of antistaphylococcal drugs is more likely to delay the emergence of resistant organisms, as it does in the chemotherapy of tuberculosis Strains of staphylococci made resistant to vancomycin in vitro retained their sensitivity to other antibiotics, suggesting that so far there seems to be no cross-resistance between it and other antibiotics This is a point of some importance, for new antibiotics are not really welcome unless they remain therapeutically distinctive Chemically similar analogues of antibiotics tend to have the same disadvantage of cross-resistance, and they are no more helpful when given in combination

Annotations

WELCOME TO A CENTENARIAN

AMONG the long established medical weeklies of the world, the *Nederlands Tijdschrift voor Geneeskunde* is individual alike in character and in the way it is managed Formerly the journal of the Netherlands medical association, it became after the war a purely scientific weekly, and its ownership passed to a separate society, of some sixty members, who produce it for the benefit of the medical profession Both the editor and the assistant editor hold university chairs (Dr J R Prakken in dermatology at Amsterdam and Dr J W Duyff in physiology at Leiden), and the only full-time medical member of the staff is the secretary (Dr M M Hilfman), but they have the help of a small board, consisting mostly of professors, who serve for three years and afterwards become members of the society Last week, when the journal started on its second hundred years, it changed its familiar small format for a larger one with double columns, which its friends will come to like even better Normally there are English summaries of all the articles, but the century opens with a special issue composed of some of the best contributions previously published The story of the last fifty years is told in a commemorative volume, by Dr C T van Valkenburg

At the decorous but cheerful celebrations in Amsterdam last Saturday, the other centenarian medical weeklies were represented by the editors of the *British Medical Journal*, the *Ugeskrift for Læger*, and *The Lancet*

HUMAN RELATIONS

THE Tavistock Institute of Human Relations has the responsible and exacting task of providing training and conducting research in the social sciences related to psychological medicine and acting as consultant to industrial organisations Government departments, and community services It is heartening to learn that, thanks to the support of American foundations, its annual budget for this work in the coming years will be of the order of £100,000 About half of this will go to the projects which the institute has undertaken jointly with the Tavistock Clinic and the other half to independent social-science programmes outside the medical field

From the start of the National Health Service, the North West Metropolitan Regional Hospital Board has supported the educational work of the institute, especially through the postgraduate courses offered at the Tavistock Clinic for psychiatrists, psychologists, child psychotherapists, and social workers External courses have also been run for general practitioners, public health workers, teachers, probation officers, family care workers, and industrial personnel officers, including students from overseas For this side of its work the institute received last year from the Old Dominion Foundation £89,000 (to be spent over seven years) and from the Grant Foundation £25,000 (to be spent over three years) which was given specially for the training of people working among children and parents

During 1956 the institute also received grants for its research The Ford Foundation gave £80,000 (to be spent over five years) and the Josiah Macy, jun, Foundation £13,000 (to be spent over three years) It is planned to extend the work of the institute's child development unit from problems arising from the deprivation of maternal care, to which it has been giving special attention, to the conditions which promote the development of a healthy personality Another research group has been making an exploratory study of a small number of London families who have different income but are otherwise alike This work grew out of experience in marriage counselling at the clinic and at the institute's Family Discussion Bureau, and towards it the Grant Foundation has given £5000 to be spent during 1956 and 1957

The Home Office, the London County Council, and British foundations which have aided the institute with this work in the past will share the institute's pleasure at this international recognition of its work and practical help towards its achievement

BODY FAT IN CHILDHOOD

"PUPPY fat" is a convenient term of abuse or of defensive hope for the future it covers, perhaps, a multitude of sins Just what it connotes anatomically, however, is harder to say Recently reliable growth curves for subcutaneous fatty tissue in childhood have been prepared, thanks to the efforts of those engaged in longitudinal studies here and in America There are four methods of obtaining information about body fat by taking soft-tissue radiographs, which enable the investigator to distinguish and measure individually the bone, muscle, and subcutaneous tissue, by pulling with the thumb and forefinger a fold of skin and subcutaneous tissue away from the underlying muscle and measuring its thickness with pinch callipers, by calculation from the specific gravity of the body, itself obtained through underwater weighing and application of the principle of Archimedes, and by calculation from the amount of body-water estimated by chemical or isotopic dilution techniques The last two of these have not yet yielded sufficient data during childhood to warrant much discussion, though potentially they are the most valid measures of the amount of total body fat, since the other methods measure only the thickness of the subcutaneous layer There is, however, good evidence [1] that the internal fat is, under most circumstances closely proportional in amount to the fat stored beneath the skin

The *soft-tissue* X ray technique was initiated by Stuart [2] and his associates at Boston, who studied the growth of bone, muscle, and fat in the calf of the leg. It has been elaborated by Reynolds[3] and his successor Garn,[4] at the Fels growth study in America, and in this country by Tanner[5] at the Harpenden growth study, where techniques have been developed for obtaining quantitative tissue growth data for arm, calf, and thigh. Measurement by skinfold callipers has a much longer history, but the results are less illuminating than they might have been because of the absence of an efficient calliper giving a constant pressure to the skinfold at all thicknesses picked up, and also of a generally agreed technique. Recently, however, a wide acceptance has been found for the Harpenden skinfold calliper,[6] and Hammond's extensive cross-sectional survey[7] of skinfolds from age 2 to 18 has been reported in these terms.

The main growth curves of subcutaneous fat are now fairly clear. From the age of 1 year onwards there is a steady loss of fat; the amount lost per year becomes smaller and smaller as the child gets older, until somewhere between five and eight there is neither loss nor gain. After this, fat gradually begins to accumulate, and this process continues to adult life, with the exception that for a year or more at adolescence boys lose fat and girls usually cease to gain it. The greatest rate of fat increase, at least in boys, is immediately before the beginning of the adolescent growth spurt, and this gain has been called the pre-adolescence fat spurt.[5] It is this period which is usually called the "puppy fat": the anxious parents can be assured that the boy will lose a good deal of this fat during the next two years; but they should also be warned that most or all of it will return during the two or three years after that, unless something is done to restrict the intake of food.

The course of events during the first year of life is intriguing and may have more profound physiological implications. The details have been clarified in a new paper by Garn[8] in which, in contrast to so many studies of growth, exemplary use is made of the longitudinal nature of the data. Between birth and three months the infant puts on a very great deal of fat; the calf subcutaneous tissue at the maximum diameter increases on average by 5·7 mm. between one and three months. Between three and six months the increase is 4·6 mm. and between six and nine months 0·7 mm. Thereafter calf fat decreases; the average infant is fattest at nine months of age. Some babies, however, start losing fat at six months, and about 15% are still gaining at one year. Though Garn's study was of the calf only, the skinfold calliper data of the Child Study Centre in London[9] show exactly the same time relations for fat over the arm and on the trunk. What is the physiological mechanism of this wave of fat deposition and withdrawal in infants we have no idea. We do not know whether fat at this period goes into the same fat cells as the fat accumulated later, or even whether its composition is the same. In trying to explain the genesis of different body builds, Tanner[10] has suggested that fat cells, like muscle cells, may be laid down in utero, and that the ability to become fat, so to speak, may be limited by the number of cells present, just as is the ability to grow large muscles. If so, one wonders whether relatively great fatness in the infant presages the necessity for diet in the adult. Or perhaps the physiology of the infant is really quite different? Clearly this period provides uncharted ground for the pædiatrician with a flair for investigation.

RESEARCH IN ROAD ACCIDENTS

IN the public eye, the bogy of road accidents has lately been obscured by some bigger ones. Though between four and five thousand people are killed on the roads every year in Britain, about as many commit suicide, many more are killed in home accidents, and four times as many die from lung cancer. But the misery (about ten people are seriously injured for every one killed) and the economic damage caused by road accidents are shocking enough, especially when we consider that nearly every casualty could be prevented by imposing a speed limit of ten miles an hour. If the public conscience condones this sacrifice to the need (or lust) for speed, the least we can do is explore every means of reducing the numbers of killed and seriously injured, both by preventing as many accidents as possible and by mitigating the severity of the rest. If St. George will not slay the dragon, he must try to blunt its teeth.

Two years ago[1] when we discussed various ways of doing this, more research into the nature and cause of accidents was clearly needed. Unless we know the most important causes of injury we cannot direct our efforts to the most profitable end. A new pamphlet,[2] prepared by the Department of Scientific and Industrial Research, gives some account of research done in the United States, where the death-rate on the roads is even higher than it is here (705 people were killed during the recent Christmas holiday). Much of this research was done at Cornell University Medical College.

The information is being gathered in three ways: (1) details of accidents and the injuries sustained in them are collected in sample areas; (2) accidents are studied experimentally, using dummy passengers, cine films, and other recording equipment; and (3) protective devices are designed and tested. Many results are to hand and have already been applied in the design of vehicles in the United States.

Many injuries fatal to the driver were caused by his chest striking the steering column. The risk can be lessened either by padding the hub of the wheel, which distributes the force of the blow over a wider area, or by using a wheel which projects several inches above the hub, so that most of the force is spent in bending the supports of the wheel. To minimise the serious injuries to the head, face, and knee caused by the dashboard or other parts of the car, these parts may be strategically padded with foam plastic. Crash-helmets would also be useful, though motorists would probably be even harder to persuade to wear them than are motor cyclists. Windscreens and doors accounted for nearly as many injuries as the steering-wheel and dashboard. The risk of striking the head against the body of the car can be reduced by safety harness, which must be attached to the frame of the car and not to the seat, for if the seat is dislodged in a collision and its weight added to that of the sitter, the force with which he strikes the body of the car will be greater. Perhaps most helpful, and less cumbersome to the motorists, are improved door-locks; for the chances of being killed or badly injured are doubled if the occupant is thrown out of his car.

Most of these devices can now be fitted to modern production models as extras if the purchaser wants them. It will be noted that they protect only those inside the vehicle, which is appropriate in a country such as the United States where three quarters of the deaths are in motor-vehicle drivers or passengers (most of the other deaths are among pedestrians and only about 1% each among cyclists and motor cyclists). But in Britain only a sixth of those who die are motorists, nearly half are pedestrians, a quarter motor cyclists, and the rest pedal-cyclists. The American findings can be used in this country and may save the lives of motorists (though different road conditions and styles of vehicles may lead to different injuries here), but it is important to find ways of protecting other road users. Some research has been done in the nature of their injuries (thus, in motor cyclists most deaths are due to head injury and the legs are damaged more often than the arms, while in pedal cyclists the arms suffer more than the legs), but there is much more to be learned. Three phases of research, similar to those undertaken in the United States, are planned, the first has begun on a small scale in Slough. Protective clothing, improved external design of vehicles to protect pedestrians, and alterations to motor cycles to protect the riders are foreseen.

Everything that can be done by improved design of vehicles must be done, but more might be gained by improving the roads and changing the laws governing those who use them. It is even more important to realise (and constantly remember) that no big reduction in the number of dead and injured can be expected until more care and skill are shown by those who use the roads.

FAST VITAL CAPACITY

THE measurement of lung volumes has long been used in the assessment of respiratory disease, and the determination of vital capacity not only is easy for the patient to understand and perform but also requires only a spirometer for its execution. The introduction of respiratory rate and capacity into lung-volume tests came with the measurement of maximum breathing capacity (M.B.C.), this measurement was designed to estimate the patient's over-all ability to move air into and out of the lungs, and the result therefore depends on the muscular effort achieved as well as on the physical properties of the lungs.

More recently the "timed vital capacity" has been advocated, in this test the patient makes a maximum volume shift of air into or out of the lungs as rapidly as possible, and the volume is recorded against time. These manœuvres give the inspiratory fast vital capacity (I.F.V.C.) and expiratory fast vital capacity (E.F.V.C.) respectively, and from the resulting curves information can be obtained about the state of the lungs, the curve itself is interpreted in one of two ways, either directly or as it relates to the M.B.C. These interpretations have been discussed by Bernstein and Kazantzis[1] and by Shephard.[2] *The direct interpretation of the curve* relies, for example, upon the measurement of the one second volume, while the interpretation of the M.B.C. is more closely connected with the maximum flow rate achieved—on the hypothesis that the M.B.C. test allows the respiratory effort to operate over the optimal parts of the E.F.V.C. and I.F.V.C. curves in such a way that the shift of air is a maximum.

Such tests, depending as they do on the measurement of rapidly changing quantities, require apparatus that can respond quickly and without "overshoot" if the results are not to give rise to misleading interpretations. Indeed, some of the earlier work on F.V.C. was carried out on the conventional heavy spirometer bell and gave false results. More recently a lightweight spirometer bell or the pneumotachograph has been used to measure volume shift in F.V.C. The pneumotachograph measures air-flow rate and requires integration over time to give volume, it has been used by Shephard[2] to investigate F.V.C. Both these types of apparatus offer little resistance to respiration, and both seem suitable for rapid F.V.C. measurements, *interference from such factors as inertia* of the bell and the temperature of the respired gas is of little significance. Shephard points out, however, *that the complex resonating system*, made up of the spirometer bell and the U-loop of the water seal, linked together by the elastic gas volume, introduces certain errors when the F.V.C. is recorded by the spirometer. These errors include the failure to indicate the true starting-*point of the manœuvre, and the obscuring of the end-point of the one second volume capacity* by bell oscillations. Shephard considers the volume delivery over the first second to be the most useful measurement derived from the F.V.C., provided that it is related to the total time of delivery, and he admits that for this measurement the errors introduced by the lightweight spirometer bell are unimportant clinically. Thus, for this purpose *the more complex apparatus* needed *for pneumotacho*gram recording and integration is unnecessary.

It is claimed, not without reason, that the F.V.C. test is much less exacting for the patient than the M.B.C. and that the F.V.C. can be made to give as much information as, or more than, the M.B.C. Though these claims are probably true, it must be remembered that it is only the volumes of gas shifted and the rate of shifting which are being measured, and not the pressures required to produce the movement. When volumes only are measured there can be no indication of the respiratory work involved, which is determined by both pressure and volume changes during respiration. In so far as respiratory work is important, as in emphysema, F.V.C. by itself provides an incomplete assessment of the respiratory state of the patient, and this view accords with the conclusions of Attinger et al. to which we lately referred.[3] Nevertheless, the F.V.C., when properly performed and interpreted, can give valuable information, and it is *a satisfactory compromise between* the extent of the measurements required and the increasingly complex and specialised apparatus necessary for the collection of important data.

THE REFUGEES

WHATEVER their plans, Hungarian doctors who have reached this country are eager to learn English without delay.

Many education authorities run courses in English for foreigners, and some propose to start special courses for Hungarians. In London application should be made to the education officer at County Hall, S.E.1, in writing or in person (room 76) or by telephone (Waterloo 5000, extension 441). The county council is waiving fees.

The B.B.C. has a series of quarter hour English lessons for those who already know some English, each day on its European service (232 metres) starting at 5 and 6.45 A.M. and 12.15, 5.15, 7.15, and 9.15 P.M. The 9.15 P.M. transmission is likely to be heard best, and at this time classes at elementary level are given on Mondays, Wednesdays, and Fridays.

Two special long playing records *to teach* English from the start have been made for the B.B.C. These are obtainable at 15*s* each, and two corresponding textbooks at 2*s* each (or 3*s* 6*d* for the two), from *the B.B.C., English by* Radio, Bush House, London, W.C.2. Cheques should be made payable to the B.B.C. Club. Alternatively, copies of the *records and books may be borrowed from The Lancet* office.

A series of five books for instruction by the direct method is published by Berlitz, and is obtainable from K. Sussapfel, Publisher, 36, Maiden Lane, Strand, London, W.C.2. The first of these costs 6*s* 6*d* (plus 9*d* postage).

Further offers of temporary homes for Hungarian doctors may be addressed *to* this office and are likely soon *to* be taken up—especially those from the London area. The fund established by *The Lancet* to meet special immediate expenses of medical refugees and their families is being distributed. Applications—and further contributions—are invited.

MEDICAL ADMINISTRATION IN MENTAL HOSPITALS *

C TETLOW
M B , B Sc Manc , D P M , D Obst
CONSULTANT PSYCHIATRIST, CENTRAL HOSPITAL, WARWICK

THE clinical side of work in mental hospitals has greatly expanded in recent years, and it is largely because of this that there is discontent among some consultant psychiatrists who are not medical superintendents I shall try to analyse the present situation from the point of view of the clinical consultant, though I am fully aware that other interpretations of this situation can be given

Perhaps the first impulse has been to stifle this discontent, or to ignore its existence , but in the long run suppression exaggerates the difficulties, whereas public discussion will lead to a constructive and healthy solution We must not forget, as Stanton and Schwartz (1954) have so admirably shown, that dissent in high places produces only one result—deterioration in the patient's behaviour and morale

Advances in treatment, a greater knowledge of the causes of mental illness, and far reaching changes in legislation have produced a greater readiness to accept treatment in the early stages of mental illness, and consequently the number of annual admissions has greatly increased In 1929, the year before the Mental Treatment Act came into force, the annual admissions to mental hospitals in England and Wales were 22,000, whereas in 1954 they had increased to 71,000 (Logan 1956) In addition there has been a considerable increase in the number of outpatient attendances at the clinics associated with the mental hospitals

All this has meant that much more time has been spent in investigating and treating individual cases Much of this work has fallen to the lot of the clinical consultant Since the emphasis has now shifted from custodial care to active psychiatry, we must ask ourselves whether the present administrative arrangements embodied in the Lunacy Act, 1890, and the Mental Treatment Act, 1930, are best suited to deal with this new burden

Results of Investigation

I have investigated the present situation by sending a questionary to clinical consultants in thirty of the larger mental hospitals in England and Wales To this I have had twenty five replies, and I am much indebted to the consultants concerned for the care they have taken in presenting the facts Briefly these are

Five consultants stated, without any reservations whatsoever, that the present methods of medical administration were completely satisfactory, and that no difficulties of any kind had been experienced

Against this, in four of the hospitals considerable dissatisfaction was expressed so much so that a near breakdown in interpersonal relationships seemed to have existed

The remaining sixteen consultants, though admitting that the present arrangements could and did work harmoniously, given a sensible and liberal interpretation of existing statutes and rules, nevertheless qualified this in some way or another

In the four hospitals where greatest friction existed, this arose largely because the medical superintendent had so interpreted the legal position as to regard himself as the final authority not only in administrative matters but also in clinical ones and had accordingly thought it his duty to authorise and select the type of treatment of any patient he wished

One consultant held that this attitude had in the past hampered the progress of mental science by certain treatments having, in some hospitals, been actually prohibited

Another said that a consultant in the mental hospital service had a much lower status than consultants in other branches of medicine

All agreed on the lack of complete responsibility felt by the clinical consultant

In the sixteen hospitals where relations were harmonious but some dissatisfaction with existing arrangements was expressed the following observations were made

Six of the consultants thought that the only realistic way to make the existing legal arrangements harmonious and satisfactory to all concerned was to have an effective, responsible, and properly constituted medical advisory committee to settle any differences in private without reference to lay committees

One consultant emphasised that the medical policy of the hospital as a whole should be constantly under review by such a committee, which should not be used solely to bolster up the authority of the medical superintendent when he found himself in difficulties with his lay-committee, as was sometimes the present tendency

Three others suggested that it was no longer possible to run a modern mental hospital on authoritarian and dictatorial lines, because this would inevitably lead to a great deal of friction and would make conditions impossible not only for the clinical consultant but also for the medical superintendent, and the people who would suffer most would be the patients

The least difficulties seemed to have arisen where the medical superintendent had direct clinical charge of some of the patients

Three of the replies showed that, in this connection, the most effective way of meeting the various difficulties connected with medical administration was the introduction of "clinical firms," one under the direction of the medical superintendent and others under that of clinical consultants, the latter having complete autonomy concerning the admission and discharge of patients under their care It is of interest here to note that the Expert Committee on Mental Health (1953) regards the treatment of each patient as "a team responsibility in which several doctors and several nurses actively participate" Even with such arrangements into teams, it was pointed out in one of the replies, it was still theoretically possible for a clash to occur, but it was equally possible for there to be no such clash and for all senior medical staff to have the status that they enjoyed in other specialties Despite these conclusions it was nevertheless felt that some authoritative clarification of existing rules should be made because of other interpretations

Three other consultants expressed the view that most of the difficulties arose because the consultant did not feel that he had complete charge of his patients, despite official assurances to the contrary

Another thought that, if a consultant in the mental hospital service did not experience a sense of full clinical responsibility, it was largely his own fault

Lay administration was recommended by two consultants, while a third thought that this would some day overwhelm us all, whether we liked it or not

One consultant was convinced that the mental hospital consultant had now come of age and no longer required a 'father figure", but another would not be a party, under any consideration whatsoever, to the formation of any Secret Society for the Abolition of Medical Superintendents

Another pointed out that, almost overnight, whether by accident or design, the position had been completely revolutionised by the introduction of the National Health Service Act in 1948, whereby clinical consultants were appointed in most of the mental hospitals, whereas they had previously been known as assistant medical officers Unfortunately a tendency persisted in some mental hospitals for the medical superintendent still to regard all the other doctors in the institution including the consultants, as his assistant medical officers, a state of affairs which caused considerable dissatisfaction

Several consultants felt a sense of frustration because the regional hospital board and even the hospital management committee appealed to medical superintendents only when seeking advice about general medical policy in matters of psychiatry

---

* Based on a paper read at a quarterly meeting of the Royal Medico Psychological Association on Nov 16 1956

Discussion

I shall state the problem as it appears to me after analysing all the opinions submitted There are two factors which are to some extent mutually at variance yet *must somehow be made complementary*

(1) *Mental hospitals differ from general hospitals* in that sound clinical administration is essential to establish within the hospital a therapeutic community in which the human and social needs of the patients (some of whom have to stay for a long time) are properly understood and adequately met (only two consultants mentioned this) It is difficult to see how such reforms as the "open-door hospital" could have come about unless the clinical administration had been in the hands of a clinically experienced medical administrator who could see the problem as a whole

Maxwell Jones and Rapoport (1955) have drawn our attention to the importance of the concept of "administrative psychiatry" and have pointed out that "informal social processes are more important to therapy than has usually been assumed" The Expert Committee on Mental Health (1953) said "that the creation of the atmosphere of a therapeutic community is in itself one of the most important types of treatment which the psychiatric hospital can provide" It is furthermore pointed out that the nearer a mental hospital approaches the organisation of the general hospital the less successful will it be in applying effective psychiatry

But, because of the changing nature of the clinical problem already outlined, such a régime is insufficient to meet the needs of psychiatry today Important though it is, it must be coupled with ever-increasing clinical treatment of each separate case

(2) *A traditional and fundamental requisite of all such individual treatment is that there should be a sound doctor-patient relationship* By this I mean that the patient should be able to look to one doctor as personally responsible for diagnosing his illness and supervising his treatment On the doctor's part it will be implicit that he will feel privileged that the patient has sought his advice, and that, if he values his reputation, he will not be content until he has given of his best The Expert Committee on Mental Health (1953) said "it is desirable that the patient, throughout his stay in hospital, should feel that there is one doctor who is his—one doctor who knows him well and whom he knows"

If such a relationship is the basis of all successful treatment, whether in general practice or in the specialties, it is especially so in psychiatry, where it is one of singular intimacy and subtlety But it is in mental-hospital psychiatry that this traditional relationship is at its weakest, as many of the replies have shown, and it is here that the fundamental conflict arises, because, on the patient's admission to the mental hospital this personal sense of responsibility felt by the consultant towards his patient is undermined In the general hospital the physician or the surgeon admits the patient to one of his own beds and has absolute responsibility for him In the mental hospital the patient, if certified, is committed in law to the responsibility of the medical superintendent, who alone can authorise his discharge, because Act of Parliament amended by Statutory Instrument (1948) no 419 paragraph 4 designates him as the chief officer of the institution

In actual practice amicable arrangements usually exist whereby the clinical consultant will discuss with the superintendent the question of discharge, but the fact remains that the superintendent has the power of veto and cannot be blamed if he uses it since it can be interpreted that he alone is responsible if anything goes wrong

The same remarks apply, though perhaps with less force to voluntary patients Whether certified or voluntary, a patient may sometimes become aware of a dispute about the advisability of his discharge He may then realise that his case is not the sole responsibility of the consultant concerned and his trust in the doctor looking after him may be damaged

Not to have complete responsibility engenders a sense of frustration, and, if the mental-hospital service is to attract the right kind of doctors, it is vital that these arrangements should be modified The Central Health Services Council (1956) states that the absence of a sufficient number of psychiatric consultants is related to the insufficient number of entrants into the specialty, the over-all shortage being about 20% of establishments

By conferring full responsibility on the consultant as in other branches of medicine, his status will be correspondingly enhanced, and potential recruits might thereby be attracted in greater numbers than at present What is perhaps more important, his therapeutic effectiveness will be strengthened, and he will come to have an accepted and authoritative position in society equal to that of the physician or the surgeon

Suggestions

Because the requirements of effective administrative psychiatry and the need to give the clinical consultant full responsibility are to some extent conflicting, it is not easy to find or to apply a remedy, but it is essential that one should be devised without undue delay, for the scope of the mental hospital as regards the mental health of the community is likely to widen to a degree unknown at present, and the mental hospital may change out of all recognition

I therefore make some suggestions as a basis for discussion

Working Party

Now that the shortcomings of the present system of administration are so apparent that the public press has become interested, it is desirable that the Royal Medico Psychological Association should appoint a working party consisting of equal numbers of medical superintendents and clinical consultants to examine this problem

If clinical consultants are to have a more effective voice in shaping the future of psychiatry, they should be better represented in the various committees of the Association The parliamentary committee of the association is composed of 29 members, of whom 16 are medical superintendents and only 2 are clinical consultants in mental hospitals In defence of this it might be argued that superintendents have a greater interest in parliamentary affairs because of their statutory responsibilities, but the membership of the education committee of the association shows a similar distribution of 34 members 24 are medical superintendents and only 4 are clinical consultants in mental hospitals

Medical Superintendents

In the present stage of evolution of the mental hospital—because of the problems concerned with the establishment of a therapeutic community—medical superintendency should continue *It is furthermore essential that medical superintendents should continue to be pre eminent in the clinical field*, for only thus can they command the respect and allegiance of their medical colleagues It is, however, difficult to see how outstanding men will be attracted to a post which daily carries more and more responsibility and less recognition It might therefore be an advantage to introduce some features of the system of medical staff organisation elaborated during the past thirty years by the American College of Surgeons and now widely practised in American hospitals generally

Under this each specialty is organised into a team under the direction of a leading clinician whose chief endeavour is to maintain a high standard of clinical work in that specialty by continued supervision, by the organisation of regular clinical conferences, and by guidance of the work and training of junior staff Such supervision does not however, go to the length of placing one consultant in the position of directing or criticising another's work, thus avoiding one of the worst features of the present mental hospital system existing in this country Upon the leading clinician devolves much administrative responsibility, and it is he who, with the help of a medical-staff committee, directly advises the lay administration on matters of medical policy.

It seems to me that such a system could well be adapted to the administrative needs of mental hospitals here, with a considerable raising of the general standard of clinical work, because the medical administrator would first have had to show that he was a clinician of the first rank. It might be objected that good clinicians do not necessarily make good administrators; but the two disciplines have much in common, and the organisation of courses in administration (already planned in this country) would do much to remedy any imperfections. The clinical consultant and the medical administrator would have a common goal, and the present regrettable tendency in the mental hospitals for a gulf to develop between them would be avoided.

The American system allows of full integration with other specialist services and with teaching and professorial departments. If such a system were applied here, the mental hospital in isolation would be a thing of the past, and it would become instead an effective unit for providing all psychiatric services to the community, and, acting through the Universities, it would in some cases perhaps also cater for the needs of students and postgraduates, which are at present inadequately met.

In this country medicine has tended to be very much of a personal affair between doctor and patient, and I have been at pains to emphasise the importance of this relationship; but there is already a tendency to organise some specialties into teams under the direction of a full-time professor, and if ever a specialty needed team-work it is psychiatry. Perhaps in some of the mental hospitals of the future the medical superintendent will come to have professorial dignity.

If such a system were adopted, it would be necessary to differentiate between the varying responsibilities of consultants, and the present methods of remuneration might therefore have to be revised.

Informal Admission

Coupled with such possible methods of administration there might also be an extension of developments already apparent in some of the more enlightened mental hospitals. I refer to the increasing tendency to admit patients informally to premises excluded from designation, as at Park Prewett, Warlingham Park, Graylingwell, and Mapperley Hospitals. Controversial issues over the admission and discharge of patients arising from the Lunacy Act and the Mental Treatment Act are in this way avoided. Perhaps we might also see the development of small psychiatric units, of 200 beds or so, attached to general hospitals and fully integrated with rehabilitation and other social services. We do not know for certain, but it might be possible in this way to prevent chronic mental illness in a large measure, as foreseen by the General Board of Control for Scotland (1956).

Sharing of Duties

It is essential that legislation should be introduced whereby the admission and discharge of patients should rest not only with the medical superintendent but also with the clinical consultant. This, together with the provision of smaller psychiatric units within the general organisation of the mental hospital, would give the consultant freedom to develop such units in his own way and in keeping with his own personality.

By all these means it should be possible for medical superintendents and clinical consultants to work together and to obviate the present tendency to a cleavage. Better understanding of the burdensome problems with which the medical superintendent has to deal might be gained if the clinical consultant could interest himself in some aspect of administration. At my own hospital, for example, I am privileged to deal with such matters as kitchen hygiene, and also the educational requirements of the nurses.

For a proper balance to be maintained it is furthermore desirable that the medical superintendent should be able to understand the point of view of the clinical consultant by himself having direct clinical charge of some beds.

Since many of the issues I have raised are controversial, it is only fair to state that at my own hospital relationships between the medical superintendent and the clinical consultants are happy and harmonious, and that many of the features I have mentioned receive de-facto recognition.

I wish to thank Dr E. S. Stern for his generous help in preparing this paper, and also the numerous consultants, whose opinions have been freely quoted, but who must remain anonymous.

THE REMUNERATION CLAIM

Statements after Meeting with Ministers

FOUR representatives of the Negotiating Committee, Sir Russell Brain, Dr A. B. Davies, Dr J. D. S. Cameron, and Dr S. Wand, met the Minister of Health and the Joint Parliamentary Under-Secretary, Scottish Office, on Friday, Jan. 4.

The Minister of Health explained that he had not given a reasoned reply to the committee's supplementary memorandum because he had been advised that there were constitutional objections to his doing so. All that he could say about the legal aspect of the remuneration claim was that, according to the advice he had received, the Government were not under any legal contractual obligation to the profession. As to the merits of the claim, he could not even begin to examine these in the present economic circumstances of the country, since this, in his view, would start a "chain-reaction" in other quarters which would endanger the country's financial stability.

The representatives of the committee vigorously opposed the Minister's attitude and emphasised, in particular, that it was not merely a dispute about money but a crisis of confidence which went to the roots of the relations between the medical profession and the Government. At the end of a fruitless discussion the Minister offered to meet the committee's representatives again after he had given further thought to the problem and discussed it again with his colleagues. This offer was accepted and it was agreed that the further meeting should take place before the end of January.

After the meeting with the Ministers the Negotiating Committee met and unanimously expressed approval of the action taken by its representatives. Later on the same day, these representatives held a press conference. By this time the Ministry had issued its own press statement, in which it had again given the figure of 137% as representing the increase which had already taken place in the average pre-war remuneration of general practitioners. The Negotiating Committee's representatives explained to the press that this was an unfair and misleading statement, since it concealed the fact that the Spens Committee had found the actual pre-war incomes to be too low. The increase over the figure agreed with the Ministry, in the light of the Spens report, as the correct average in terms of the value of money in 1939 was only 100%.

The Ministry's press statement said that the claim was for an increase of not less than 24% over present levels of remuneration (which in the case of general practitioners were on average already 137% above pre-war) The extra cost to the country would be about £20 million a year The Minister had explained that the claim had *not* been rejected but, as he had already tried to make clear, the Government were responsible to the country for doing everything they could to combat inflation, and present economic circumstances made it impossible for them to consider the claim at the moment In other words, nothing he had said expressed any opinion one way or another on the merits of the claim It simply was that it could not be afforded under present conditions Regarding the profession's contention that the Government were under a legal contractual obligation, the Minister had said that the Government were advised that this was not the case The detailed reasons for this legal advice could not be given, for obvious constitutional reasons, in case of action against the Crown in the courts He regretted that the claim could not be examined on its merits at the moment He was already actively considering how best to deal with the problems raised by these issues, and all that the Negotiating Committee had said at their meetings with him on Aug 1 and last week would be taken fully into account in this review

Public Health

Antioxidants in Food

THE Minister of Agriculture, Fisheries, and Food has announced his decision to accept, with some changes, the Food Standards Committee's recommendations on antioxidants.[1] The use of four antioxidants (propyl, octyl, and dodecyl gallate, and butylated hydroxyanisole) will be allowed, up to certain limits, in "oils and fats, essential oils and butter used for manufacture" The committee's recommendation that the use of antioxidants should be disclosed to the purchaser is to be considered

Occupations and Ages

Analysis of the complete figures on personal occupation derived from the 1951 Census[2] shows that of the occupied men 29% were aged under 30, and only 4% more than 65, of the occupied women 44% were under 30, while 5% were 60 or over 88% of men aged 60–64, 47% of men aged 65–69, and 27% of men aged 70–74 were gainfully occupied, compared with 89%, 79%, and 53% respectively in 1921

Conferences and Congresses

HOSPITAL COCCAL INFECTIONS

ON Jan 2 a symposium on hospital coccal infections was held in London, under the auspices of the Association of Clinical Pathologists, with Prof A A MILES in the chair

Dr A C CUNLIFFE pointed out that hospital infection could be defined in clinical or bacteriological term Both must be used to obtain a true picture, for *Staphylococcus aureus* could be recovered from 10% of all wounds showing no clinical sepsis, whereas wounds might break down without being infected The prevalence of sep had been falling before antibiotics were discovered, it was now rising

Dr R E O WILLIAMS spoke of the principles of investigation of an outbreak of hospital infection Sepsis should be routinely recorded, and the outbreak considered epidemiologically, bacteriologically (including assessment of the serotypes or phage types involved), and hygienically thus if one type only was involved there was likely to be a single source, but if there was more than one type there might be some general or specific lowering of aseptic standards Phage group I was common in maternity units and group III in surgical wards

Dr B R FRISBY (Oxford) described two outbreaks of staphylococcal diarrhœa, these involved 31 patients (of whom 14 died) including 14 who had undergone gastrectomy (of whom 7 died) All had had antibiotics, but only 5 had had broad-spectrum antibiotics The onset and course were rapid, with rice water stools and collapse Pathogenic staphylococci were found all over the ward, which was quickly infected by a single patient Dr Frisby recommended that antibiotics should be given to surgical patients only when there was a definite indication, and then the patient should be isolated, side wards were ineffective for this

Dr E J LOWBURY (Birmingham) agreed that staphylococci of phage group III predominated in burns, and wondered whether the decreased incidence of streptococcal infection was due to a reduced virulence of the organism Dr FRISBY said that 1 case of staphylococcal diarrhœa had followed neomycin therapy, and that in his cases smears of the stools were loaded with staphylococci, indicating that these probably caused the diarrhœa and were not an incidental finding 6 patients had responded to erythromycin Dr O M LIDWELL spoke of the advantages and drawbacks of various methods of ventilation, and Prof J W HOWIE (Glasgow) said that an inefficient steriliser was worse than useless, for it could concentrate polluted air

Theatre Infections

Dr R A SHOOTER gave an account of the sharp drop in wound sepsis (9% to 1%) when the ventilating system of an operating-theatre was changed so that air was no longer sucked in It was useful to have a brisk horizontal flow of air over the table

Dr R BLOWERS (Middlesbrough) said that a wound could be assumed to have been infected at operation if sepsis quickly followed, if there was deep but not superficial sepsis, or if infection was persistently associated with the presence of a certain person in the theatre Experiments with a slit sampler had shown that the contamination of air could be reduced greatly if movement in the theatre was restricted to the minimum necessary, if the patient was put in position on the table before he was brought into the theatre, if everyone in the theatre wore proper clothing, and if blankets were not used In half the septic wounds the same organism was present on the patient's skin, more attention might be paid to its sterilisation

Dr D B **MOORE** (Exeter) said that long operations and self-retaining catheters predisposed to wound infection There was a higher incidence of infection with virulent staphylococci if an "umbrella" of antibiotics was used

Dr W A **GILLESPIE** (Bristol) said that after 1081 operations there had been 85 staphylococcal infections, it was thought that 19 had originated in the theatre and 55 in the ward Staphylococcal wound infections arising in the ward were often due to phage-group III, and furunculosis to phage-group I which was found in the nurses' noses

Ward Infections

Dr **LOWBURY** spoke of burns He said that primary excision and grafting was the best prophylactic measure against infection When grafting must be delayed, infection could be reduced by dressing burns in an air-conditioned room using a no touch technique, and by using chemotherapeutic creams If *Streptococcus pyogenes* appeared, specific chemotherapy should be given The exposure method probably did not protect burns against contamination

Dr **JANET JELLARD** said that in nurseries the babies, which were often handled without gloves and with inadequate hand-washing, were the chief reservoir for infection The umbilical cord was especially dangerous and should be either covered or treated with an antiseptic

Dr E S **DUTHIE** (Southampton) described an outbreak of infection due to phage-type-80 staphylococcus in two general hospitals in the same group There were infections of the skin, eyes, wounds, bedsores, and urinary tract, and bronchopneumonia but no enteritis He agreed that babies were a reservoir of infection, and had found that prompt isolation of infected patients and staff was helpful, and that reducing the number of nasal carriers and the dust content had some effect

Dr J D A **GRAY** said that strict attention to cleanliness and asepsis in nurseries was essential Many staphylococcal infections, though resistant to other drugs, were sensitive to chloramphenicol and erythromycin, eye infection responded to sulphonamides and cord infection to gentian-violet Streptococci might survive penicillin treatment because of coexistent penicillinase-producing staphylococci Dr J G P. **HUTCHISON** (Newcastle upon Tyne) agreed with previous speakers that babies are the culture medium, infecting their mothers and other patients Dr M H **GLEESON-WHITE** (Cambridge) mentioned 15 cases of rapidly fatal hæmorrhagic staphylococcal bronchopneumonia All of them had probably had pulmonary œdema

Investigation and Control

Dr **WILLIAMS** listed the steps in the investigation of an outbreak These included keeping a theatre and a ward book recording all infections, and watching ward and theatre techniques as they were carried out in practice

Prof **RONALD HARE** described experiments showing that nasal carriers produced air contamination owing to infection of the skin and clothes, movement, dressing, washing, &c, spread the organisms more than did sneezing or talking A few carriers contaminated the air much more than the rest

Dr J C **GOULD** (Edinburgh) spoke of methods of reducing contamination by carriers Creams containing common antibiotics such as penicillin and tetracycline were the most effective in eliminating staphylococci from the nose, but these had drawbacks, and a mixture of neomycin or bacitracin and chlorhexidine ('Hibitane') was almost as effective In practice such creams reduced the incidence of auto infection and cross infection

Dr **BLOWERS** emphasised that laundering did not sterilise blankets, but heat sterilisation ruined them Woollen blankets could be sterilised about twenty times by a quaternary ammonium rinse after laundering He showed three experimental blankets that could be boiled, they were made of terylene, turkish-towelling and a cotton weave, and were respectively much more, a little more, and less expensive than woollen ones

Dr H B **MAY** spoke of the administrative aspects He said that one consultant in each hospital should concern himself with all hospital infections there All infections should be notified to him by the ward sisters He should investigate infections and advise on prevention and treatment The infected patient cost half as much again as the uninfected patient

Dr **MARY BARBER** said that staphylococci in pus were probably more virulent than those in the noses of carriers, it was therefore important to separate septic surgical patients in wards and operating-theatres Dr H G H **RICHARDS** (Winchester) said that hospital overcrowding predisposed to infection and that more and better hospitals were needed

GASTRO-ENTEROLOGY

A **CONFERENCE** on gastro-enterology, under the auspices of the Postgraduate Education Committee of the University of Glasgow and of the Royal Faculty of Physicians and Surgeons, was held on Nov 26–30

Treatment of Ulcerative Colitis

Dr S C **TRUELOVE** (Oxford) said that in the treatment of ulcerative colitis the correction of fluid and electrolyte depletion, particularly that of potassium, was important Blood-transfusion and administration of cyanocobalamin (vitamin B_{12}) or folic acid were valuable, oral iron should be avoided The diet should have a high protein and calorie content, in those with anorexia, a fortified intragastric milk drip was given at night Either cortisone, prednisolone, or corticotrophin could be given, and oral cortisone could be combined with the daily instillation by rectal drip of hydrocortisone Colonic dispersal by this route had been found satisfactory, and there were rapid remissions in many cases Antibiotics reduced the risk of pyogenic complications, and propantheline relieved abdominal pain

Dr W I **CARD** (Edinburgh) emphasised the considerable protein loss and the intensive replacement needed Surgery should be avoided during the acute phase if it were needed cortisone should be discontinued In surgical treatment Prof J C **GOLIGHER** (Leeds) opted for primary colectomy with permanent ileostomy Occasionally, irritation of the adjacent skin or stenosis of the stoma followed Mr A B **KERR** recommended primary ileostomy in some cases, with colectomy later The ileostomy bag need not be adhesive Dr **BERNARD LENNOX** said that biopsy of colonic mucosa was valuable in investigating the disease Often large areas of mucosa were shed this loss was irreparable and influenced the results purely medical measures

Peptic Ulcer

According to Mr R A. **JAMIESON**, the true prevalence of peptic ulcer in this country was about 10% for men and 3% for women These figures were based on post mortem series Mr D H **CLARK** said that before puberty boys and girls had an equal incidence of peptic ulcer, but after puberty ulcer was many times more common in males 90% of women had a remission of ulcer symptoms during pregnancy, but symptoms always recurred Onset or aggravation of symptoms was common at the menopause

Dr A. R **CURRIE** drew attention to the association of peptic ulcer with islet-cell tumours of the pancreas The risk of malignancy in gastric ulcers was probably less than had previously been believed, it was estimated that only 4% of gastric cancers routinely examined had arisen from chronic peptic ulcers

Prof T F RODGER said that in many cases the onset of symptoms was associated with emotional upset Studies in the United States suggested that ulcer patients had intense unconscious dependency wishes An "ulcer type" was no longer recognised

Dr L D W SCOTT suggested that the association between peptic ulcer and coronary-artery disease might be explained by the *customary high fat* diet of ulcer patients Of 110 men admitted to his wards with myocardial infarction, 20 (18%) had peptic ulcers, of 89 controls with bronchial carcinoma 8 (9%) had ulcers

Dr S LAZARUS said that rest in bed was the most important single factor in medical care and increased the rate of healing of both gastric and duodenal ulcers, it was more valuable in hospital than at home Diet, milk drips, and drugs might relieve symptoms, but did not seem to influence the rate of healing of an ulcer

. Mr A P M FORREST said that, in view of the risk of malignancy, gastrectomy should always be performed for gastric ulcer In duodenal ulcer an attack on the acid-producing mechanism was essential Gastrectomy was *probably still the treatment* of choice, *but* where it was inadvisable (as in the patient with pulmonary tuberculosis, the female, the poor risk, and where it was technically hazardous) vagotomy, with pyloroplasty or gastro enterostomy, was suitable In gastric ulcer the Billroth-I gastrectomy was preferable, but in duodenal ulcer it carried a high rate of recurrence, and a Polya reconstruction was advisable

Mr W T IRVINE said that patients in the fourth and fifth decades were particularly liable to develop stomal ulcer This was a complication of gastric operations only when they were performed for peptic ulcer, it might appear many years after gastro-enterostomy but usually within three years after gastrectomy These ulcers had a particular tendency to penetrate Marginal ulceration following gastro-enterostomy was treated by gastric resection and reconstitution of the jejunum involved in the anastomosis, but for recurrent ulcer after gastrectomy a higher resection was usually the *treatment of choice Vagotomy might help patients* in this group

The post gastrectomy syndromes were described by Mr A N SMITH Their incidence was directly proportional to the amount of stomach removed The small capacity of the gastric remnant, increased rate of gastric emptying, reflux into the afferent loop, hypoglycæmia, jejunal distension, osmotic influences, alterations in blood volume, and disturbance of acid base balance had all been cited as possible causes of these syndromes He advocated a high protein and high-carbohydrate diet and eating meals dry, soups should be forbidden Potassium citrate, local anæsthesia, and ganglion blockers might relieve *symptoms*, in severe cases conversion to Billroth I gastrectomy gave good results

Mr A W KAY discussed the management of bleeding peptic ulcers and suggested that they were, in the first instance, amenable to medical treatment Operation was rarely advised for the initial bleeding, when the mortality was low, or for the long term recurrence which in all respects resembled an initial hæmorrhage On the other hand, surgery should always be considered in patients over the age of 50, as in this group the mortality rose steeply or when there was a history of a chronic ulcer, particularly if this was gastric An acute ulcer was unlikely *to cause fatal bleeding* Surgery was undoubtedly required where there was continuing or rapidly recurring hæmorrhage where there were added complications of the ulcer (perforation or stenosis), or where pain persisted after the initial bleeding At operation the presence of blood in the gastric aspirate and the level of blood in the gut were guides to the site of bleeding If no ulcer was palpable or visible and the bleeding was *coming from* the stomach, an acute ulcer was the most likely source The presence of an enlarged lymph node *at the origin of the left gastric* artery was suggestive of a gastric ulcer If no source of bleeding was apparent the stomach was not to be opened but a blind gastrectomy performed If examination of the excised specimen did not reveal the lesion causing the bleeding the gastric remnant was inspected and any lesion dealt with

Treatment of Carcinoma of Colon

Professor GOLIGHER said one would expect to save half the patients with carcinoma of the rectum Three quarters of the cases seen were operable Local fixation of the growth, as estimated on rectal examination, was a completely untrustworthy sign of inoperability Palliative resection should be performed wherever possible, $1^{1}/_{2}$–2 years of comfortable life might be obtained by the patient with liver metastases For growths below the peritoneal reflexion, abdominoperineal resection was indicated If the growth was in the upper third of the rectum, low anterior resection gave as good results and *maintained a continent anus Lesions* here would be more than 10 cm from the anal verge on sigmoidoscopy and just within reach of the palpating finger The only certain sign that the blood-supply to the anastomosis was adequate was arterial bleeding in the cut mesocolon or bowel If there was doubt as to the integrity of the anastomosis, a temporary transverse colostomy was advisable, an extraperitoneal drain was left in place for 7–8 days In acute obstruction due to cancer of the right colon, immediate resection and anastomosis was usually possible, if the ileocæcal valve was incompetent and the ileum distended it should be decompressed by catheter In obstructing lesions of the left colon, either transverse colostomy or cæcostomy would relieve the obstruction In obstructing lesions of the transverse colon, the colostomy should be placed next to the growth for the cancer and colostomy could be simultaneously excised later

Mr KERR said that, as cancer of the rectum rarely led to obstruction, a palliative colostomy should never be performed Radiotherapy was beneficial for perineal recurrence

Gastro-intestinal Hormones

Dr CARD said that the evidence for the presence of humoral factors in the intestinal tract of man was not good It was now possible to localise accurately and study the cells of origin of a hormone, by administering the appropriate antihormone, which caused a reaction in the [illegible] cells The blood supply to the stomach was enormous, 50 volumes of blood was required to produce 1 volume of 0 16 *M* HCl 0 004 µg of histamine per kg body weight per hour (a dose well within the physiological range) *by* constant intravenous infusion could induce acid gastric secretion He believed that gastrin was a histamine liberator The use of secretin was well established in the diagnosis of pancreatic disorders In relapsing pancreatitis the administration of morphine with secretin prevented a flow of pancreatic juice and reproduced the pain After sphincterotomy the test gave a good flow of pancreatic juice and no pain Recent reports had suggested that pancreozymin contained a gall bladder contracting substance Fat in the duodenum inhibited gastric motility and secretion by release of the hormone enterogastrone, which inhibited all types of gastric secretion and protected dogs against the development of peptic ulcer after the Mann Williamson operation Urogastrone, the excretory product of enterogastrone was known to inhibit histamine and induce gastric secretion in man

Mr H I TANKEL suggested that histamine could stimulate pancreatic secretion—an effect blocked by atropine Mr SMITH presented data which demonstrated that extracted gastrin liberated histamine in all tissues

In England Now

A Running Commentary by Peripatetic Correspondents

Now that the well-informed have disposed of the *Times's* Christmas tests of knowledge, they may care to try the menu of last Saturday's medical banquet in Amsterdam. The outside presented few difficulties:

Singulæ Dapes (it said) appositae in Epulis Sollemnibus Nonis Ianuarus MCMLVII propter Ephemeridem Neerlandicam pro Medicina centum annos vigentem.

But now we came to the essentials:

Promulsis cum cancro
Ius testudinis in calice
Vinum ex vinea aulica Wehlenensi MCMLIII
Summa solea more archimagiri
Solana tuberosa Britanno modo
Phasianus assus
Brassica salita ornata
Poma cocta mixta
Vinum ex vinea Beinæ MCMLIII
Casei selecti
Placenta ex ovis cocta glacie sub spuma latente
Vinum spumans siccum (Perrier Jouet)

It was about 20 to 1 when we adjourned for

Cafæum
Coniacum et liquores

feeling that the evening had been well begun.

* * *

Not far from the American border in this part of the world there used to be a place called Fort Whoop Up where American whisky traders ran trading-posts to sell liquor to Indians in Canada. This led to such lawlessness that a body of men known as the North West Mounted Police established itself in the same area under Colonel McLeod at a place that has become the town of Fort McLeod. Fort Whoop Up is now nothing but a Historic Site.

Times change. The N.W.M.P. has become the R.C.M.P. The provincial government has established trading-posts known as government liquor stores where any man who pays fifty cents for a permit can go and buy as much hard liquor as he likes, provided he pays for it and is not Indian. Gasoline in abundance from local oil-wells provides power to drive cars at high speeds, faster than the fastest horses of the days of Fort Whoop Up. By these means many casualties enter hospitals, and some go to the funeral parlours. Many cars are wrecked and prosecutions for "impaired" driving bring revenue to the government in addition to the profit from the liquor stores and the gasoline tax.

This whooping-it-up state of affairs is mildly endemic throughout the year, but about Christmas and New Year it used to become epidemic, until a few years ago when the Alberta Safety Council began to deal with it prophylactically. The council is helped by the newspapers and radio stations and their advertisers, commercial firms, motoring organisations, and the city police in Calgary. Here cars may be seen bearing curious bumper legends such as "Drive like Lightning, Crash like Thunder." Another jingle of the campaign is "Stay Alert, Stay Alive, Make it Coffee when you drive." Badges distributed to truck-drivers bear the motto, "No thanks, I drive a truck." A distillery advertises that "Men who think of Tomorrow practise Moderation Today."

The culmination of the campaign is at the peak of the epidemic. In Calgary since 1950 the police will, by request, drive you home on Christmas Eve and New Year's Eve if you lack sobriety but retain wisdom. The too convivial driver will be driven home, and his car will be driven home too if there is somebody to take charge of the keys. Otherwise the car will be parked overnight and may be claimed when the owner recovers. This duty is undertaken by unpaid volunteers of the police department, and no charge is made for their services. It is strictly understood that their attitude is one of sympathetic assistance, and that no action will be taken against the driver who asks for help and doesn't drive. But the most awful penalties are promised to him who is found to be "impaired" and driving. The year this service was started the number of accidents over Christmas and the New Year fell from 65 to 13 and has never risen above 12 since. Calgary's methods may be unorthodox but they seem to be effective.

* * *

Singing at work must be as old as man. The Hebridean woman churning milk, the Negro slave chopping wood, the sailor hauling in the mainsail, and the boatman with his Volga boat, were all employed in monotonous physical tasks rendered tolerable and even pleasurable by a sort of mass hypnosis. A happy custom, and we are the worse for losing this capacity to burst into an appropriate lyric when about our everyday chores. It is good news, therefore, that a Cobbleigh Committee is sitting at Widdicombe-in-the-Moor to select occupational songs for the medical profession.

Two Lovely Black Eyes is suggested for casualty officers, and *Dry Bones* for orthopædic surgeons. Cardiologists will trill *Boom, Why Does my Heart Go Boom* in close harmony between patients, and pædiatricians will take readily to *Sleep, Baby, Sleep*. This song was put forward first for anæsthetists, but *Two Sleepy People* was felt to be more appropriate. Of contemporary songs, *Shake Rattle and Roll* might suit the physiotherapists, and *Rock Around the Clock* the maternity department. The committee is not neglecting the Greater Medical Profession: medical statisticians will have the first 99 verses of *One Man Went to Mow*, and hospital administrators and home sister *You Can't do That There 'Ere*. For the rest of the nurses *Tea for Two* is suggested. For psycho analysts there was a wide range of choice. *My Dreams are Getting Better all the Time* was considered, but in the end the committee recommended the old song that goes *We've Been Together Now for Forty Years, and it Don't Seem a Day Too Much*.

* * *

The Medical Superintendent had thrown a Christmas party and was gazing out of the window with pride at a gigantic fir tree in the grounds which was blazing with coloured lamps. A visiting psychiatrist clapped him on the shoulder.

"I say, old boy, that's a terrific show; how did you get the lamps?"

"Oh, they are just replacements from the stores and we got the depressives to spray them with lacquer."

"Yes, but who foots the bill for the extra current?"

"There isn't any."

"How come?"

"Oh, we just replaced all the hundred watt bulbs in the nurses' home with twenty fives."

* * *

I believe an ancient word for physician meant "one who knows urine," and many old pictures of the physician show him holding up a vessel of urine to the light. My old chief used to start his round in the side-room where the urines of all his patients were displayed in conical glasses. All this seems to have gone now and urine has become a rare commodity. Nurses are tidier than ever and all specimens are sent quickly to the path. lab. or sluiced away. I no longer see urine but only typewritten slips of paper describing it.

* * *

I was driving along a quiet country lane on my morning round when a small car, driven by a woman, shot out of a side turning and came to a sudden stop alongside me. She gesticulated wildly and shouted "Pig!" I was somewhat taken aback at this and, feeling much aggrieved, I wound down my own window, shouted "And pig to you!" slammed into gear, and drove round the corner where, wandering in the road, was the largest pig I'd ever seen.

* * *

One of my junior colleagues preferred to avoid the contacts and the accuracy involved in claiming mileage. Now "they" won't give him petrol coupons. I have been trying to push his case, but

Letters to the Editor

FUTURE OF NURSING

SIR,—I should like to give complete support to Dr Ritchie Russell (Dec 15) The statement of policy from the Royal College of Nursing must surely have been formulated after a study of the report of the Nuffield Provincial Hospitals' Trust on "The Work of Nurses in Hospital Wards" (1953), yet its aims are in many ways out of harmony with this The report pointed out that those State registered nurses who remain in the hospitals spend their time in the main watching student nurses do the actual work And it is generally well known that few SRNs do in fact devote themselves ultimately to the techniques of nursing

The new proposals seem to increase these tendencies, so that one may justifiably ask what will be the object of becoming a trained nurse

Anyone who has recently visited hospitals in the United States will have noticed the *reductio ad absurdum* which the craving of nurses for academic status has created in that country In hospitals other than those staffed by nuns, the graduate nurses in charge of beds tend to sit majestically at desks outside their wards, doing the "office work" and making critical (though often pertinent) comments on such matters as the blood chemistry of their patients The real nursing is done either by orderlies or by the patients' relatives

In medicine the aim of most of us in qualifying is to practise our craft, very few of us become medical administrators or devote ourselves wholly to teaching So should it be in nursing

Finally, if the nurses and the doctors are in the future to belong to parallel services, what is to be the fate of the patient? Whose will be the ultimate responsibility for his care? Many of us have noticed with concern a growing lack of acceptance by senior members of the nursing profession that they belong to an auxiliary service which must be subordinate to the doctors, and which cannot possibly have an independent existence If the Royal College of Nursing made public acknowledgment of this fact, and used its influence to ensure that nurses in training are given the same opportunity to live their personal lives as is accorded to students in other spheres, nursing would have no lack of recruits

Radcliffe Infirmary
Oxford

RONALD MACBETH

SIR,—I would like to endorse the views put forward by Professor Vining and Mr Brian Watkin (Dec 29), and also to thank Professor Vining for his admirable statement of the complex range of duties for which nurses must now be trained

A further point which might be emphasised is the numerical importance of nurses in the National Health Service It must be recognised that senior members of the nursing staff, in both hospital and public health services, generally carry direct responsibility for the work of a greater number of people than the senior officer in any other section of the services Unless these leaders have good intelligence, a sound knowledge of the principles of administration, and the wisdom to deal with a wide range of human problems, wastage will be severely aggravated

The age of entry into training needs further consideration, but although it seems necessary to establish a minimum, should this be chronological age alone? The patient, male or female expects from the nurse a maternal attitude, and this is developed by girls at varying ages Some girls of 17 are more mature than others of 19 If an accurate assessment of maturity could be made, this would be more important than age in years

The pressing problem of the status of the State enrolled assistant nurse urgently demands attention and perhaps the easiest step towards improvement would be a change in title to "State enrolled nurse" It is regrettable that the Royal College of Nursing, in its otherwise valuable statement on policy, has not recognised the need for promotion. Team-work would offer more interesting duties to the S.E.A.N., but would this alone be sufficient to attract recruits in the numbers we require? Ambitions may well soar higher than providing "a much needed stable element in the team" Is there any reason why experienced assistant nurses should not become ward sisters in certain fields, particularly that of geriatrics, in which their reputation is so firmly established? They should be, at least, as good as the inexperienced and sometimes inadequately trained State registered nurse

Lastly, with regard to the vexed question of "common entry" versus two types of training, is Dr Ritchie Russell not aware of the generally accepted principle that students of widely different intellectual ability cannot be taught together? If they could, the 11+ examination and A B, and C streams in the schools would be superfluous If it is agreed that nursing has room for women of different levels of intelligence and academic ability it is surely reasonable to accept two streams, or types of training

I would like to allay some of Professor Vining's fears about picking "'high ups' at the start of training" Certainly a university course should not be a passport to high office It should only give a better preparation for leadership to the candidate who also develops the qualities of mind, personality, and character needed by the leader It may also be hoped that some of those who would have the advantage of a university course would choose to remain in the field, in close contact with patients, just as some of our most able members today remain as ward sisters, health visitors, and district nurses, instead of stepping into administration The influence of these women who have the ability for senior appointments, but choose the more practical aspects of nursing work, cannot be overestimated

Leeds

JOYCE M AKESTER

SIR,—We have long advocated a scheme of training like that suggested by Dr Ritchie Russell Its purpose is to encourage recruitment and to avoid on the one hand the wastage due to inability to pass the State examinations and on the other the alleged frustration of the more intellectual candidate

The assistant nurse scheme recognises and has proved the value of the "ordinary nurse," and it is surely absurd to speak of downgrading a nurse's status by teaching her the basic technique of nursing We consider that the minimum age of entry for hospital training should be reduced to 17, that candidates must have reached a reasonable standard of general education, and that the present assistant-nurse training and "assessment" should be taken by all candidates, and should lead to qualification as a "State registered assistant nurse" No difficulty should attach to postponement of the assessment in the case of the slower candidates, nor should there be any slur upon those who continue for the rest of their lives in this grade There should, however, be a grade of "senior assistant nurse," with higher pay, obtainable by promotion by those who have served for say ten years in a hospital

During the two years of basic training it will have become evident which nurses are fitted for advanced training These candidates, who should possess the General Certificate of Education or equivalent general educational qualification, should proceed to a third year of training and to an examination in the theory and practice of nursing to enable them to qualify as "State registered nurses" This training, in our opinion, should include a course in pharmacology, and State registered nurses should have the same duty as the pharmaci to question dosage No one should become a hospital staff nurse without this qualification, and no one should be appointed sister who has not had a minimum experience of one year as a staff nurse in either a general or a special hospital

For those of academic ability and inclination there is already a diploma of nursing obtainable at London

University This might be taken by aspirants to teaching or higher administrative posts Nursing, in our view, is a subject totally inappropriate to a university curriculum leading to a degree.

C M OTTLEY

Hove Sussex.

SIR —Lest Dr Thomas Anderson should again be disappointed I hasten to write in support of his letter of last week.

For many years I have been personally concerned with the teaching and training of nurses in two very large mental-deficiency hospitals During that period I have seen the standard of nursing raised considerably, only to fall again The General Nursing Council are now the only examining body for mental nurses, and the preliminary examination of that body is quite inadequately related to the experience which a first-year student nurse gains in the wards The syllabus for that examination makes no mention of the nature of mental illness, or of mental defect, of the special needs of such patients, or of the reasons for the special methods used in nursing them On the other hand, the academic level required in anatomy, physiology, communal health, and bacteriology has been steadily raised

The number of female nurses who complete their training as mental or mental-deficiency nurses is quite inadequate, and the proportion of trained nurses has fallen to a dangerously low level

The Ministry of Health is now pushing forward a scheme for the instruction of ' nursing assistants "—clearly with a view to introducing a grade in mental nursing corresponding to the State enrolled assistant nurse The inefficient handling of mental patients can produce results which are very serious for the patient, and which raise serious difficulties in administration This official attempt to perpetuate the present shortage of trained staff can only result in a lowering of the standards of care and treatment available for mental patients

Like Dr Anderson I take the view that it is our duty, as the doctors responsible for the care of these patients, to protest, and to do whatever we can to impress upon the Minister of Health that nurses must work under the direction of doctors, and that senior medical staff in every branch of medicine should have a much greater influence in prescribing the standards of training and examination of the nurses who have the immediate care of patients

In conclusion, may I underline one of Dr Anderson s points ? What our hospitals need are far more ordinary nurses—i e , staff nurses, trained to undertake the routine care of patients efficiently From their ranks will emerge those capable, after further training of accepting the responsibilities of the higher nursing posts

D J ROSE

X RAYS AND LEUKÆMIA

SIR,—We appreciate the way in which Dr Rabinowitch (Dec 15) has clearly depicted the fundamental issue at stake—that is whether there is a threshold dose of radiation below which leukæmia in man is not induced Dr Rabinowitch weighs the evidence and concludes that such a threshold is likely to exist and that it may lie between 100 and 200r , in our view the present evidence is insufficient to justify this belief

The principal weakness in Dr Rabinowitch s argument is that he has not adequately taken into account the very large numbers of persons who need to be studied in order to establish the presence or absence of an effect from doses of radiation as low as those that may be received during the course of diagnostic radiology Thus on the assumption of a simple proportional relationship between dose and effect, a reasonable estimate is that a dose of 1r averaged over the red bone-marrow of the whole body would cause about 1 case of leukæmia annually in a population of 1,000,000 people Bearing in mind that in the general population, aged 15 years and over, the incidence of leukæmia is approximately 50 cases per 1,000,000 persons per year it can be shown that about 20,000 000 persons, each exposed to a mean marrow-dose of 1r in excess of that received by the general population, would probably have to be observed for a period of ten years before the excess of cases could be recognised. If the average marrow-dose were about 20r, a population as large as about 50,000 persons would need to be observed for the same period Even the latter project would be formidable but it is not impossible ; and we must face the fact that if this important problem is to be solved, projects may well have to be mounted on this scale

It is not perhaps generally realised that similar limiting conditions have also been found in the investigation of the incidence of radiation-induced gene mutations According to Muller, the lowest radiation dose level at which it has been possible to observe the excess of lethals resulting from the irradiation of drosophila sperm is 25r[1] Nevertheless, above this level the form of the relationship between dose and response is such that geneticists have postulated with considerable confidence that no threshold dose exists for the induction of gene mutations, and this postulate has been accepted in practice

With regard to Dr. Rabinowitch s specific arguments, we would make the following comments

(1) It is not to us, surprising that none of the children of the 205 women who were pregnant when they were exposed to the atomic explosion at Hiroshima have developed leukæmia In fact only 4 of the mothers were exposed at distances of under 1000 metres and 145 were 2000 metres or more from the hypocentre From data published by the United States authorities,[2] estimates can be made of the doses of prompt γ-radiation that would have been received by persons standing unprotected in the open at varying distances from the point of explosion. These suggest that the dose at 1000 metres would be not less than 1400r and at over 2000 metres it would be not more than about 8r[3] The dose resulting from such fallout as occurred in Hiroshima is not likely to have increased the total doses substantially above those resulting from the prompt radiation The fact that the women exposed at less than 1000 metres survived, indicates that they must have been heavily shielded from irradiation, presumably by buildings, as a dose of 1400r to the whole body would cause acute radiation death in all persons Many if not all, of the mothers exposed at greater distances would also have been shielded to some extent, so that on average these mothers, even those 2000 metres or more from the hypocentre, will have received appreciably smaller doses than those estimated above While, therefore, all these mothers, and their children may have suffered some increase in their probability of developing leukæmia, it is our view that the population exposed was far too small, relative to the doses received for it to be likely that even one case of leukæmia would have been subsequently observed either amongst the mothers or their children

(2) With regard to the general incidence of leukæmia among survivors in Hiroshima and Nagasaki, Dr Rabinowitch argues that no increase has occurred among persons exposed beyond 2000 metres and that doses of between 100 and 200r must have been received at this distance since many instances of ' radiation sickness ' have been reported Like many others interested in the problem we believe that such reports of radiation sickness should be treated with reserve It has already been pointed out that the available physical data suggest that survivors exposed at more than 2000 metres received doses

---

[1] Muller H J Radiation Biology New York 1954, p 476
[2] Effects of Atomic Weapons New York 1950
[3] Medical Research Council Report Cmd 9780 H M. Stationery Office 1956 p 15

of not more than about 8r of prompt γ-radiation, and radiotherapeutic experience shows that whole-body doses of X rays of this order do not cause radiation sickness The most likely explanation of the reported instances of "radiation sickness" is that a feeling of malaise with some nausea, and even frank vomiting and diarrhœa, may occur in anyone subjected to sufficient physical and emotional stress However, the data on the ratio of the observed number of cases of leukæmia to the expected number at varying distances from the hypocentre among Hiroshima survivors show that there is, in fact, a steady fall from about 100 to 1 for those exposed at less than 1000 metres to about 1 5 to 1 for those between 2000 and 3000 metres and that the ratio is still above 1 to 1 (i e, 1 2 to 1) for those over 3000 metres[4] The numbers of cases are, however, too small to be able to conclude that the incidence has definitely been increased at these two latter distances The populations of survivors are estimated to be 30,350 and 37,350 persons respectively, and the data refer to an eight-year period of observation As has already been pointed out, a population of 50,000 persons exposed to a mean marrow dose of as much as 20r may well have to be observed for a period of ten years before any significant excess of cases of leukæmia can be recognised

(3) Dr Rabinowitch quotes our own preliminary data on the incidence of leukæmia in 13,352 patients treated with X rays for ankylosing spondylitis,[5] and points out that, whereas 35 cases of leukæmia were found in those patients who had received a maximum dose in the spinal marrow of 500r or more, only 2 were found among those who had received doses of less than 500r These data, however, should not be taken as evidence in favour of a threshold effect, for, if they are taken at their face value, it must be concluded that the number of cases observed at each level of dose is, in relation to the number of patients exposed, proportional to the dose received and hence the data tend rather to support the hypothesis that no threshold dose exists

(4) The data on radiation-induced leukæmia in animals are complex and the conclusions based on them can be applied to humans only with the greatest caution—if at all In the first place, there exist considerable species differences in susceptibility, and leukæmia is less easily induced in the dog, the guineapig, or the rat than it is in the mouse There now seems little doubt that man has a higher sensitivity to the induction of leukæmia than many other mammals Secondly, most animal observations have been made on mice, and Furth and Upton and other writers have now shown that in this animal 3 different forms of leukæmia may be induced—a thymic lymphoma, a non-thymic lymphoma, and a myeloid leukæmia The facility with which these various tumours are induced seems to depend on several factors apart from radiation, such as the breed of mouse, sex, age at the time of irradiation, hormonal state, &c Certainly, Furth and Upton did report that the combined incidence of both types of lymphoma in untreated ageing RF male mice was about equal to that in their group of male mice exposed to neutron irradiation, up to biologically equivalent doses of about 500r[6], but it is probably unwise to generalise from such observations to man—particularly since Furth and Upton reported an increase of myeloid leukæmia in their irradiated animals, and human radiation induced leukæmias are mainly of this variety Thirdly, it is only within the last year that the problem of the incidence of leukæmia in relation to low levels of radiation has assumed such importance Published animal experiments have not been designed to investigate this particular point, if they had been, the experimental designs would have been different and the numbers of animals used much greater

In conclusion, we should like to point out that leukæmia is only one of the delayed effects of irradiation It so happens that to date most attention has been paid to this effect, but there are undoubtedly others such as the production of other tumours, and there is also the possibility that there may be a general effect on the expectation of life, to which attention has been recently drawn by Shields Warren[7] Such effects may be additive, and the total risk run by a given individual after a given radiation dose will presumably not be fully described by his enhanced risk of developing leukæmia But whether it is proper to extrapolate from existing data and to estimate quantitatively the size of the very small effect to be anticipated with the low doses used in diagnostic radiology is uncertain It is evident that, in this era when the medical and industrial uses of atomic energy are expanding so rapidly, it is of basic importance to determine whether threshold doses for the induction of these delayed somatic effects exist

HEAD INJURIES

SIR,—One has reason to believe that 80% of casualty cases are first seen at non teaching hospitals,[8] and that most of these hospitals are faced with the problems outlined in your leader of Dec 22 It is, in fact, a great credit to the casualty departments in this country that the mishaps you refer to are so few, when there is no clear policy that I have ever heard of for the disposal of head-injury cases brought in the first instance to outlying hospitals I have puzzled over it for many years and am little further on than when I started The only course one can adopt is to admit everything one possibly can and to hope that the inevitable piece of bad luck will land on some other hospital's doorstep

In deciding what to send on to the neurosurgical centre the situation is little better One cannot, in all fairness, send everything, and one seldom knows what proportion of those sent have profited by it I do not believe one should send head injuries merely because they are severe It may be, as we are told by the neurosurgeons, that patients with head injuries travel well, but many are moribund when they are first seen, and it is wrong that someone who is going to die should do so in an ambulance or soon after admission to a strange and sometimes distant hospital Not only is it wrong, but it may be said that the transfer precipitated the fatality, and it is hard to hold to a theoretical opinion in the face of an individual tragedy The casualty officer or the inpatient emergency surgeon is often faced with a dilemma—to risk the upset of these mishaps, or to hold onto a case which might profit by prompt transfer I find it very difficult to give a confident prognosis soon after a severe head injury, and the silent extradural hæmorrhage can deceive anyone Moreover, clinical judgment must be tempered by knowledge of transport and other resources because the disposal of accident cases is almost as much a geographical problem as a surgical one (My suggestions for improvement in this direction have been described as "semi military,"[9] but I do not know if this was intended as half a compliment or half a criticism)

The present development seems to be to put small neurosurgical "metastases" from the regional centres into suitable peripheral hospitals, as soon as the multiplication of neurosurgeons is adequate to staff them But how far is this to go? Do we aim at a head injury unit at every crossroads, and if so, how much will it cost and how long must we wait to get it?

It would, to my mind, be much more sensible, as well as much less expensive, to integrate and educate the resources at present available for selecting these cases and for carrying out such preliminary treatment as will help any later specialised procedures They are admitted to *our* wards or seen in *our* casualty-rooms We want to know, more precisely than we do at present, what type of case need not be transferred, what type it is useless to transfer, and, most particularly of all, what should guide us in deciding whether to send a case on, to ask a neurosurgeon out to see it, or to get on with it ourselves

---

Neurosurgical units are busy, progressive institutions, but a new operation for cerebrospinal rhinorrhœa, or a post-mortem report on ruptured œsophagus (though I find them interesting enough) are of little practical value to us "on the periphery" We would welcome a clear lead from them on the points I have mentioned, covering a problem which (if your figures can be applied more generally) affects 50,000 Britons every year

Sunderland T. G Lowden

DANGEROUS CONTAMINANTS IN STORED BLOOD

Sir,—Apparently Dr Discombe, who wrote last week, infers from my letter that the contamination-rate in consequence of opening bottles of blood for cross-matching in hospital laboratories is 5 1% , but, for the reasons stated in my letter, this is not so Neither hospital pathologists nor transfusion-laboratory directors can help it if bottles of blood opened in their laboratories for cross-matching are again opened. but not used, in wards or operating-theatres Such opening is bound to increase the contamination-rate

As to pilot tubes, I have no desire to embark on a discussion on so controversial a matter except to say that pathologists and technicians having the necessary training can, and do, sample bottles of blood with very low contamination-rate Also, it has to be borne in mind that occasional bottles will be contaminated at phlebotomy In either event the contaminating organisms will probably always be non-pathogenic Provided the blood is used within the prescribed period of opening the bottle, and refrigeration of the blood is constant, no harm is likely to ensue in transfusion, as experience has abundantly shown Trouble from infection of blood is, of course, only too likely to arise from mishandling of blood after it has left the laboratory Without doubt the taking of samples of blood from bottles, and the cross matching of blood, should never be permitted by any persons—doctors or technicians—lacking the appropriate training and experience For obvious reasons the same rigid standards of aseptic technique in taking blood samples ought to apply to pilot tubes as to blood bottles

Regional Transfusion Centre
Phyd Lafar, near Cardiff R Drummond

Sir,—Dr Discombe states that bacterial contamination kills about 1 in 350,000 Dr Drummond (Dec 15) finds that 5 1% of entered bottles are contaminated Dr Discombe hesitates to enter the main bottle and relies on the pilot bottle for all his tests I consider that pilot bottles are reliable , but not all pathologists agree—they quote cases where the pilot bottle contained blood antigenically different to the contents of the main bottle One has to see their point of view There will be general agreement that it is undesirable to enter the main bottle unless some strong indication exists—e g , to give "packed" cells Even so contamination can be reduced to a minimum by using a long sterile steel needle for suction and a second needle guarded by an air-filter for the ingress of air Dr Discombe may get his figure of 1 in 350,000 from published statistics The objection here is that not all deaths from this cause are published , it is possible that some are not even suspected The procedure for establishing that death was due to contaminated blood can be quite difficult Even if the bottle of blood is removed during the course of the transfusion—without exposure to the air—and taken immediately to the laboratory, where tests are performed without delay, the blood still may have been contaminated at the time of use, and not at the time of taking from the donor or during storage

As blood escapes from the main bottle and enters the veins of the recipient, every volume of blood is replaced—while the blood is flowing—by an equal volume of air Strictly, this replacement air should be filtered Only too often it is not because the drip has stopped or slowed and someone finds that the rate of flow can be restored by removing the filter Possibly, also, the filter has become wet with blood, and constitutes a real obstacle It is sometimes possible to detect contamination of the blood in the main bottle by careful inspection (without removing the bung) The well-known line of hæmolysis at the junction of plasma and cells, the gas bubbles caught in the top layer of plasma, or the gas sometimes seen bubbling up through the cells into the plasma are all indications Once a bottle has been shaken it is difficult to detect contamination by inspection, in the absence of a bottle centrifuge, for which I should like to make a plea

Another useful sign is a loose bung This is a rare occurrence with modern equipment. but only a few years ago a loose bung was not very rare A loose bung allows contaminated air to be sucked into the main bottle while the contained blood from the donor is cooling from body-temperature down to 4°C A perfect bottle of blood from a donor after cooling should contain a slight negative pressure When the bottle is opened for actual use the absence of this negative pressure, or a slight positive pressure should make the user suspicious Such an occasion would justify the test recommended by Dr Aidin (Nov 17 and Dec 22) on the particular bottle under suspicion Desperately ill patients have more than one bottle of blood prepared , the transfusion can continue with another tested bottle while the one that behaved suspiciously while being opened is subjected to the procedure recommended by Dr Aidin

Epping Essex Frank Marsh

ERADICATION OF TUBERCULOSIS

Sir,—Dr Beresford (Dec 22) draws attention to the incompleteness of notification of tuberculosis This defect is concisely illustrated by the 1500 cases each year whose tuberculosis is not known to public health authorities until revealed by death certification

The reasons for the failure to notify tuberculosis include

(*a*) Apathy on the part of doctors in hospitals

(*b*) Assumption that cases have been previously notified when in fact this is not so

(*c*) The view that the disease cannot ethically be disclosed to anyone except the person suffering from it

(*a*) It is understandable that those whose skill is concerned with the craft of treatment should overlook their menial duty of notification , but nevertheless, where courtesy fails it is the statutory duty of the medical officer of health to initiate proceedings against defaulting medical practitioners This duty is evaded

(*b*) The regulations require *every* medical practitioner who forms the opinion that a person is suffering from tuberculosis to notify the disease If he has grounds for believing that the case has already been notified, the medical practitioner diagnosing the diseases is *not* asked to refrain from notifying it

(*c*) We all tend to accept as an ethical necessity the practice of the mass radiography units of keeping confidential the names of those cases considered tuberculous , *but the fact* is that, when the director of a mass radiography unit forms the opinion from X-ray examination that a person is suffering from tuberculosis, his statutory duty is to notify the case to the medical officer of health

The value of notification lies not so much in its statistical use as in the help it gives in revealing tuberculosis among the contacts of the person notified

Dartford, Kent J H HUDSON

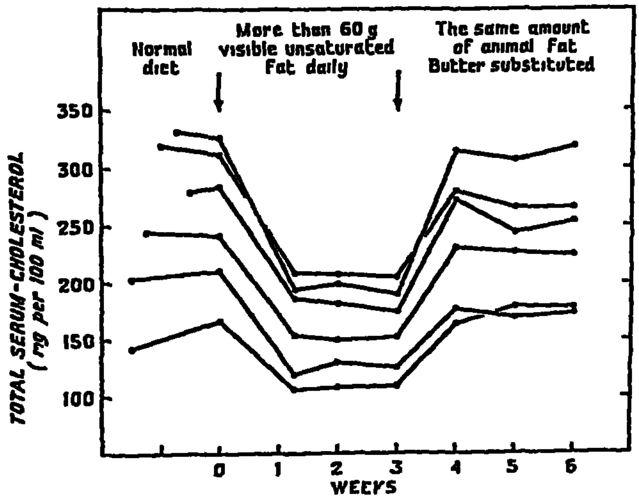
FATS AND DISEASE

SIR,—The reopening of the correspondence (Dec 8, p 1211) on your leader of April 28[1] demonstrates how widely this argument occupies medical thinking

Whilst Dr Gopalan confirms that sesame oil, which contains about 40% linoleic acid, lowers the serum-cholesterol level, Dr Gofman and his colleagues state that "the vegetable fat was not seen to have any specific lowering effect" It is important to realise that certain unsaturated fats seem to have not an absolute but only a relative lowering effect on the serum lipid level The workers at the Donner Laboratory say that there were *no significant differences in* S_f *0–20 lipoprotein content* during the two experimental periods when their subjects derived 8% of their calories from mixed fat or 43% of their calories from non-hydrogenated cottonseed oil But when the proportion of fat calories consisting of animal fats rose to 45% of the total daily caloric intake, the S_f 0–20 lipoprotein class was raised by 39% as compared with the period when approximately the same amount of fat was given (i e, 43%) but in the form of non hydrogenated cottonseed oil Thus there was a very definite difference in the S_f 0–20 lipoprotein class when approximately isocaloric amounts of vegetable and animal fats were compared (the carbohydrate intake being practically the same)

I have previously referred to some preliminary experiments[2] using pure corn oil and wheat germ oil for lowering the serum cholesterol level Meanwhile I had the opportunity of administering corn-oil products in a more palatable form[3]

The chart shows clearly that during the period of changing over to corn oil an immediate and substantial lowering of the serum-cholesterol proportional to the initial cholesterol level occurred When corn oil was replaced by fats of animal origin a rebound took place within a week's time The diet of these six patients was calorically not controlled The intake of visible animal fat was, however, limited to *about one teaspoonful* of butter daily on their toast at breakfast Unavoidably they obtained some further fats of animal origin in their food, which contained, besides unlimited amount of carbohydrates, at least 4 oz of lean meat, or 6 oz of lean fish, daily Hence their protein intake was adequate Wholemeal bread, plenty of fresh green vegetables, and fresh fruit were taken Tinned food was eliminated During the period of experiment the patients had incorporated into skim-milk and cheese, at least 60 g corn oil daily (which contains 55–60% of linoleic acid) and an adequate supply of vitamins



My experiments were of short duration, but I have since seen patients in Lund kept on a similar diet for many months, with a continuous lowering of the serum cholesterol level[4][5]

Though recognition of the cholesterol lowering effect of certain vegetable and fish oils is of great scientific importance, the application of any conclusion derived from it to a complex condition such as coronary atherosclerosis calls for great caution A generation ago Aschoff was already teaching that deposition of lipids in the intima of arteries cannot be expected under any mechanical condition unless hypercholesterolæmia is present Only under the impact of concerted post war research (discussed repeatedly in your columns during the past year[1][2][6–8]) it has been assumed "that any dietary factor that raises or lowers the level of β lipoproteins in the blood will also, by implication, raise or lower the liability to myocardial infarction"[1]

The most difficult aspect is that in a patient with moderate atherosclerosis a comparatively small plaque somewhere in the coronary tree may give rise to gross myocardial infarction, whilst patients with severe generalised atherosclerosis may escape a coronary catastrophe for a long time Coronary, but not generalised atherosclerosis has been prevented, or even made regressive, in animal experiments,[9] but this difference in the production of the atherosclerotic lesions has not so far been observed in man According to hospital statistics atheroma formation appears, if anything, to be no more extensive now than it was thirty to fifty years ago,[10] but the rapid increase of myocardial infarction in recent *decades is real*[11][12] *and, as a common* disease, it is new, not merely newly recognised[10]

For nearly a hundred years, under the impact of *Virchow's cellular pathology* and Pasteur's discoveries medical thinking was concentrated on finding one single causative factor of disease The concept of a multiple ætiology, rediscovered and applied to coronary heart disease, might explain some of the hazards linked with recent investigations Coronary heart disease encountered at the bedside is the end product of several processes developed through many years partly unnoticed, in which quite different stimuli, singly or together, lead to the same pathogenic response—hypercholesterolæmia In the past *I have discussed some of these* apparently not interconnected stimuli,[13] and have mentioned that on a fat-poor diet emotional stress may elevate the blood cholesterol level[14] May I add a few more points which were taken into consideration in the experiment represented in the chart?

In highly industrialised countries, where the greater part of the population is engaged in full time work in factories and offices, the tendency since the end of the first world war has been towards manipulating and processing food The food industry has become more and more efficient in the presentation of foodstuffs and also in improving their quality This 'improving' however, has many hidden pitfalls To mention one example we are rightly assured that the modern canning process is so effective that canned fruit or vegetables often have a higher ascorbic acid content than fresh fruit or vegetables stored for a long time But it has only recently become known that the pyridoxine content of canned or processed food may be reduced Nutritionists were seriously alarmed when Elvehjem found that American army combat rations used in Korea, consisting of a large variety of processed foods, were deficient in vitamin B_6 as judged by their effect on rhesus monkeys[15] Other much-praised army rations containing highly processed ham, pork meat, and eggs were inadequate for rats, but they could be made good by substitution with freshly processed similar food[16] Dr Sinclair has emphasised in your columns[6] the importance of the pyridoxal enzyme system in the intermediary metabolism with regard to the conversion of linoleic into arachidonic acid and also the importance of flour of high extraction-rate In order to prevent even marginal vitamin-B_6 deficiency, my patients received wholemeal bread, only fresh fruit and vegetables, and a generous supply of pyridoxine with their vitamins

Another aspect of possible vitamin deficiency has to be considered if unsaturated fatty acids are given to patients for a longer time or permanently Already the discoverer of essential fatty acids found that during his experiments the vitamin-A stores in the experimental animals became depleted[17] Antagonistic effects of linoleic acid on carotenoids have been previously attributed to oxidation[18] As the normal adult liver carries a vitamin-A reserve sufficient for a year or longer[19] and our patients obtained at least 10 000 I U of vitamin A with their daily vitamin supply, no signs of deficiency could be detected during the short time of this experiment

The easy oxidability of unsaturated fatty acids is not necessarily heralded by a rancid pungent odour especially during the earlier stages when only the labile peroxides are involved There is now overwhelming evidence that the dietary intake of polyethenoid fatty acids seriously interferes with the metabolism of at least 15 species of farm and laboratory animals The exact mechanism of this metabolic disturbance is as yet unknown, but the action of the poly-unsaturated fatty acids—mainly present in marine oils—seems to affect the capacity of the tissues to utilise the potential free energy of the ingested food[20] The resulting pathological lesion affects the whole muscular system leading to a muscular dystrophy involving occasionally the myocardium with changes in the E C G , the extent of the lesions seems to vary in the different species of animals[21] Most of these "metabolic injuries" can apparently be prevented or corrected by the administration of α tocopherol[22] Vitamin E being the most powerful physiological antioxidant, will possibly prevent any oxidative rancidity in the intercellular metabolism even at the expense of its own destruction The possibility of precipitating vitamin-E deficiency by administering unsaturated fatty acids was considered during our experiments The corn oil used contained at the time of preparation about 108 mg vitamin E per 100 ml and this might have adequately protected my patients In future experiments of longer duration it would however be absolutely necessary to follow up the serum-tocopherol levels

In conclusion, there is every reason to believe that man is unable as yet to adapt himself quickly to the plentiful and sophisticated food offered to him wherever Western civilisation penetrates in force This type of nourishment, together with the Western way of life, uniformly raises the serum-cholesterol level independently of race These factors seem to be instrumental in producing early and extensive arterial changes and possibly altering the whole clotting mechanism Replacement of animal fats by certain oils containing essential fatty acids reduces the serum-lipid levels If this reduction could be maintained permanently a novel approach for the treatment (and more so for the prevention) of coronary atherosclerosis would have been gained There is urgent need for more extensive and coördinated research as inevitably there are some drawbacks connected with the rapid changing of long-established food habits No doubt new lines seem to have been opened to nutritional research, in which modern food industry is bound to take its part I completely agree with Schroeder,[9] however, that though it may still take a long time to prove the reversal of arterial lesions by lowering the blood-cholesterol level in man, we now have tools with which more extensive investigations can be undertaken without great risks or inconvenience to patients

TOWARDS TELEVISION GASTROSCOPY

SIR,—In their most interesting letter of Dec 22 Prof Henry Wallman and Dr Bengt Rosengren report their trials with a midget television-camera assembly inserted into the stomach In Rheims Dr Dubois de Montreynaud is routinely demonstrating endoscopic views on closed-circuit television in black-and-white to visitors to his clinic He uses the Fourestier-Vulmiere-Gladu type of endoscope to project the field of view into a light-weight television camera developed for this purpose by Monsieur Minot While we must wait with interest to see which of these two teams first produces practicably useful colour-television images, I feel the French system preferable in principle, because it is sensible to keep high-voltage television equipment outside the patient's body

London W 1 BRIAN STANFORD

THE USE OF PLASMA

SIR,—In recent correspondence the relative merits and the cost of plasma and dextran have been discussed[1] Some observations concerning costs and also the capacity of these products to correct hæmostatic defects require further comment

To attach a theoretical price to a bottle of plasma is misleading and it is more useful to think in terms of actual expenditure in the conditions prevailing

Plasma can be prepared from outdated bank blood which has not been used for transfusion As the outdated blood is already available, and would otherwise be discarded, it has no intrinsic financial value, and the cost of plasma prepared from it is that of the processing If, however, more plasma is required than can be obtained by processing outdated bank blood then blood must be collected specially for the purpose, and this must be taken into account in assessing the cost of the extra plasma Whole blood has been priced variously at figures up to £2 per bottle , assuming a cost of 30s per bottle, the minimum cost of producing a 400 ml. unit of plasma (requiring 2 bottles of whole blood plus processing) is of the order of £3 10s

Dried plasma prepared from outdated bank blood immediately after the expiry date is a useful source of the stable clotting factors However, for the treatment of deficiencies of labile clotting factors (i e , antihæmophilic factor and labile factor [factor v]) fresh plasma prepared from specially collected

---

1 Rainsford S G Lancet 1956 ii 849 995 1264 Wallace J Ibid p 945 Clarke P, Ibid p 995

Dr. Robert Fleig Library

blood is essential, and in view of the increasing quantities being used it is worth emphasising that this product costs at least £3 10s per 400 ml unit (Thus to maintain a hæmophiliac on three bottles a day costs £10 10s per day for the plasma alone)

To sum up, the following products are available

1	Whole blood	£2	per bottle
2	Plasma from outdated blood	under 10s	" "
3	Additional plasma from blood specially collected for the purpose	£3 10s	" "
4	Fresh plasma to provide labile clotting factors	£3 10s	" "
5	Dextran	£1	" "

It appears that outdated blood available from the transfusion centres could provide sufficient stored plasma for all peace time civilian needs, and therefore for civilian use the cost of plasma for routine use should be taken at the lower figure of under 10s

Under normal conditions up to 20% of blood collected is not used as whole blood and is available for conversion to plasma On this basis, the 1955 figures for blood collected in England and Wales indicate that about 80,000 bottles of plasma could be prepared from the outdated blood, and in fact this is approximately the amount manufactured The figure for dried plasma used in the same year is under 40,000, so a considerable surplus of the less expensive plasma is available

Regarding the clotting factors, Admiral Rainsford, in his second letter, states

> "Plasma recovered from stored blood or stored for any length of time in the liquid state has little or no hæmostatic properties and is known to produce hæmostatic defects —perhaps because of the large amount of citrate it contains "

It is true that plasma stored for three to six months at room-temperature, or treated with kaolin, is unsatisfactory as a source of clotting factors, but it is not widely thought to produce specific hæmostatic defects, nor does the presence of citrate cause an adverse reaction, except possibly in a very rapid massive transfusion

Further, dried plasma prepared directly from time expired blood is a useful therapeutic source of fibrinogen, and other stable clotting factors, although fresher plasma might be used in preference in a patient with a known deficiency Stefanini and Dameshek [2] state that plasma up to 20–30 days after collection can be used for the treatment of hypoprothrombinæmia, stable-factor (factor VII) deficiency, plasma-thromboplastin-component (Christmas factor) deficiency, plasma thromboplastin-antecedent deficiency, afibrinogenæmia, and fibrinogenopenia If such plasma is available, it should be used in the treatment of shocked patients, if there is a likelihood of a clotting-factor deficiency, rather than dextran, which itself tends to cause a coagulation defect In giving emergency treatment to patients with hæmorrhagic shock it should be remembered that such a clotting defect may already be present and a watch should be kept on clotting function In particular, fibrinogen deficiencies may arise in (*a*) various hæmorrhagic complications of pregnancy, (*b*) any condition involving very extensive tissue damage, whether through burning, injury, or surgical procedures

Caution has been advised in the use of large volumes of dextran,[3] and it has been suggested that for the time being it is best to limit the amount of dextran given to any one patient to one litre Stable liquid plasma freed from active hepatitis virus by storage at room temperature would provide a satisfactory alternative for patients with no sign of a clotting defect, but as Admiral Rainsford has pointed out, the problem of bacterial contamination has yet to be dealt with In the case of clear filtered, kaolin treated plasma, the contamination difficulty is less serious as the clarity of the final product is an indication of sterility However, before this product can be widely useful it is necessary to evolve a technique for kaolin treatment which will give a more stable product than that obtained by the original Maizels method[4] which remains clear for only a few months

To sum up, dextran and other plasma substitutes being free from the danger of serum hepatitis, are useful for the emergency treatment of oligæmic shock However, *in patients who require a large* transfusion, or who are likely to have a clotting-factor deficiency, blood or plasma are usually to be preferred, as their clinical value outweighs the danger from hepatitis

DRUMMOND ELLIS

FIBRINOLYSIS AND ATHEROSCLEROSIS

SIR,—Will you permit some rather belated comments on Dr Astrup's review [5] *of the biological significance* of fibrinolysis ? There has been considerable discussion in the medical press over the revival by Duguid [6] of Rokitansky's hypothesis, advanced more than a hundred years ago, that atherosclerosis follows mural fibrin thrombosis Duguid's conclusions are based on his observations of thrombotic fibrin-layers which become altered and incorporated in the vessel wall to form atheromatous plaques His contention that this process of mural thrombosis is a recurring phenomenon, with successive fibrin deposits on the endothelium resulting in cumulative thickenings, is aided by my own concept presented in 1953, which serves as a theoretical basis for vascular alterations involving the endothelium [8]

I consider the inner or "endo endothelial" lining of the vessel wall to be a fine porous film of fibrin, produced and deposited on the layer of endothelial cells continually during life Disturbances in the physiological process which produce and maintain this fibrin coating throughout the vascular system are thought to lead to thrombosis or hæmorrhage Thus on the one hand increased production and deposition of fibrin, or decreased fibrinolysis, would result in thrombosis, while conversely reduced production and deposition of fibrin and increased fibrinolysis would result in hæmorrhage

Macfarlane and Biggs [9] were the first to describe increased fibrinolysis after strenuous exercise and after adrenaline injection and to emphasise its occurrence in anxiety states, thus suggesting that fibrinolytic activity is a physiological process According to Macfarlane [10] there is no destruction of fibrinogen in naturally induced fibrinolysis As there seems *to be normally* a steady fibrinolytic process, probably affecting primarily the endo endothelial lining, there must be a concomitant and continuous repair of this fibrin film, thus securing the integrity of the endothelial wall

There seems to be a highly intricate system of mechanisms which facilitate the formation of the fibrin film on the endothelial cells In the marginal plasmatic zone of Poiseuille, which is free of cellular elements practically no blood flows, thus permitting sufficient reaction time for the formation and deposition of non-gelated fibrin, as well as for fibrinolysis *The inter*endothelial spaces permit the infusion of tissue juice containing many factors which, upon mixture with the plasma, result in reactions concerned with fibrin formation and fibrinolysis Various *coagulation promoting* factors, present in tissue juice activate thrombin form its prothrombin complex and associated factors The steady infusion of minute quantities of heparin-like materials, released from the mast cells in the subendothelial and perivascular connective tissue, may not be enough to prevent the formation of fibrin particles, but, because of the antigeloplastic effect of heparin, aids in the prevention of vascular occlusion as well as in the maintenance of the fluidity of the blood We do not know what constitutes an intact endothelium, and it is not known whether the endothelial cells participate in fibrin formation and fibrinolysis—a field of study in which I am at present actively engaged

[10] Macfarlane R G *C R 3rd Congr Soc int Europ Hemat* Rome 1951 p 719

In support of the concept of the endo endothelial fibrin film, recent observations are of interest Levene[11] examined the electron-microscopic structure of apparently normal aortic intima and found superficial fibres, obtained by scraping, indistinguishable from fibrin Even though some objections can be raised to Levene's conclusions (e g , the teased-off specimens do not provide exact knowledge as to their position in the intima, and the periodicity, which Levene gives as a criterion, may not entirely suffice to differentiate between collagen and fibrin), it cannot be stated with certainty that this protein film is not fibrin Finally, there are our findings on the hæmorrhagic effects of fibrinolysin (plasmin), and on the production of vascular purpura in guinea-pigs by guineapig antifibrin serum of rabbits[12] It is of interest that Kowalski and his associates[13] found, after streptokinase activation, greater fibrinolysis in the intima as compared to the other layers of human aorta and other human tissues

Astrup, too, contends that in the healthy organism small amounts of fibrin might be deposited on the walls of arteries However, his view appears to differ fundamentally from mine, since he limits this deposition to arteries, especially when strain causes tissue damage, and thinks that these deposits are removed by the fibrinolytic system as rapidly as they are formed In my view the continuous deposition and maintenance of the endo endothelial film takes place physiologically in all blood vessels throughout life

Moreover, the known occurrence of hæmorrhage due to an increase of fibrinolytic enzymes in the bloodstream cannot be explained merely by a fall in antiplasmin and the disappearance of fibrinogen as discussed by Astrup[14] It seems more likely that hæmorrhages are produced because the introduction of plasmin into the circulation, as I have shown, directly affects the vessel wall, and in particular the endo endothelial fibrin film This I consider also to be the explanation for hæmorrhage produced by an in-vivo coagulation defect or by the introduction of an anticoagulant into the bloodstream Some authors claim that heparin increases fibrinolysis, while Astrup found that it inhibits fibrinolysis Be that as it may, it is of interest that mast cell counts made in the vascular wall in atheromatous human aortas were found to be increased Sundberg[15] relates these findings to the fact that granules of the mast cells contain a heparin-like substance and to its effect on certain lipoproteins Another aspect which needs to be clarified is whether cholesterol and certain lipoproteins have a special affinity to fibrin surfaces

It is premature to reach any hard and fast conclusions about fibrin deposition, fibrinolysis, and atherosclerosis, but my concept of the new rôles of fibrin and fibrinolysis gives the findings of Duguid and his associates a physiological basis

SHORTAGE OF RADIOGRAPHERS

SIR,—I must deplore Dr G H Illingworth's views on radiographers (Jan 5)

My experience, previously as a qualified radiographer, and later as a doctor, persuades me there are no grounds for complacency regarding the average standard of radiography in this country I believe that consistently first class work is the exception, and where I have met it, it has invariably been done by radiographers who thoroughly understand what they are doing, and the apparatus with which they are doing it

To lower the standard of entrants to the profession, would, I think, be undesirable , but to lower the standard of teaching would be disastrous The former would be inevitable if, as Dr Illingworth seems to suggest, the best posts were reserved for selected male students If there are enough girls sufficiently foolish to train as radiographers under such circumstances, the standard of work to be expected from them must be abysmal

Incidentally, how would Dr Illingworth select his male students ?

Milford Chest Hospital
Godalming Surrey

W JOAN FERRABY

SIR,—I entirely disagree with Dr Illingworth There is widespread dissatisfaction among radiographers concerning their quite inadequate remuneration, the retiring age, and the terms for " on call " As a radiologist I agree wholeheartedly with their viewpoint

As regards superintendents, Dr Illingworth is seeing the problem from the point of view of the large teaching hospital In the majority of regional board hospitals, the radiologists are part-time and cannot attend to the details of organisation and the endless queries which need experienced handling, and the radiographer in charge, whether superintendent or in smaller hospitals senior in grade, has to carry a heavy responsibility, not only for the standard of work but for the care of the patients also I should not care to have the work in my department carried out by young girls of a lower educational standard with such inadequate training as is suggested Not all hospitals are within a short journey of the nearest manufacturer !

St Stephen s Hospital,
London S W 10

GRACE BATTEN
Consultant Radiologist and
Medical Superintendent.

SIR,—Concern about the inadequate remuneration is certainly not confined to a few male radiographers At a recent meeting of the North East London Radiographic Group more than 60% present were females and all expressed strong dissatisfaction with the recent award

All schools are permitted to admit students at the age of 17 and a number already do so No student, however, is allowed to come into contact with patients until the age of 17½, and the qualifying age remains at 20 This seems an eminently reasonable policy

The recently published Medical Research Council report on The Hazards to Man of Nuclear and Allied Radiations has indicated that the greatest radiation danger to the general population in peace time comes from diagnostic radiology Far from diminishing, diagnostic radiology will be used on an ever increasing scale if it is to continue playing a crucial part in the investigation of the patients It is essential therefore that measures to minimise the radiation hazards of diagnostic work be improved The person who will be primarily responsible in minimising these grave hazards should not only be versed in the art of positioning and correct exposure of films but have an understanding of the basic principles of physics and apparatus construction to make him/her a safe and understanding operator Surely " an intelligent girl of 17 or 18 with an aptitude for the work " will not be satisfied with being a mere push button and deprived of any possibility of deriving intelligent stimulation from her work

What sort of girl is going to take up radiography where there is no prospect of any intellectual satisfaction or any advancement in professional or financial status ?

Dr Illingworth suggests that the way out of our serious difficulties is to use the cheapest and least refractory labour force available and bring the whole profession down to the lowest common denominator This may be the easiest way but it is the least satisfactory It reflects an attitude of mind that is unfortunately too common in many walks of life today If his views prevail not only will a disservice be done to the profession of radiography but patients, medical staff, and not least radiologists themselves, will suffer

London, N 19 H M HARROTT

DIVERSION FOR THE PATIENT

SIR,—It is reported that background music will be played in order to calm patients undergoing obstetric operations under local anæsthesia Do doctors ever think of asking patients what they find helpful and comforting during such ordeals? And, quite apart from whether the patient finds music helpful, who is to decide what music shall be played? Some patients would want only the latest hit song by their favourite crooner, others might have Third Programme tastes

Surely in these days it is not beyond the bounds of possibility to have specially gifted women whose job would be, first to get to know the patient and her case, then to be at her side throughout her ordeal One is constantly meeting young mothers who complain that throughout their labour no one had time to speak a word of comfort or reassurance to them And this they remember long after they have forgotten their pains But I have yet to meet one who said "If only the radio had been on—or television"

Braunton Devon WINIFRED CUMMINGS

MYOPATHY IN SHEEP

SIR,—In your issue of Dec 29, Dr Bosanquet, Dr Daniel, and Mr Parry again mention the occurrence of vacuolated nerve cells in the medulla oblongata of sheep affected with scrapie, and they quote in full the opinion expressed by Dr Holman and myself[1] that "clinical symptoms suggestive of scrapie followed by microscopic discovery of vacuolated nerve cells in the medulla oblongata probably constitute sufficient evidence on which to base a positive diagnosis of the disease" We would like to state that we have found no evidence since these words were written to cause us to alter or to modify that opinion

Our conclusion was based on examination of 75 sheep affected with scrapie, 39 sheep dying of diseases other than scrapie, and 39 other sheep that were clinically healthy when slaughtered Two to six sections of the medulla were examined from each case, and the relationship of the presence of vacuolated cells to clinical scrapie gave a χ squared value of 155, with P less than 0 0001 We made it clear, however that the mere findings of vacuolated cells after death was not pathognomonic of the disease, because they were occasionally found in animals that had not shown clinical evidence of scrapie For this reason we emphasised the importance of observing the typical clinical symptoms in establishing a positive diagnosis We recognised then, as now, that very clinical cases of scrapie may show only a few vacuoles histologically, but in other cases vacuolation is far more extensive than we have ever seen in clinically healthy sheep killed for examination, or in sheep dying from other diseases An example of such a case was given in our paper, where 167 serial sections through the medulla gave a count of over 37,000 vacuolated cells

I have recently examined sections of the medulla oblongata from goats affected with scrapie, and here *again, as in sheep, I have no doubt that vacuolation of* nerve cells is characteristically associated with the disease This work is not yet complete, but counts of vacuolated cells made to date may be of interest

	Number of sections examined	*Total number of vacuolated nerve cells found*	*Range of number of vacuolated cells per section*
16 clinically healthy goats	592	8	0 to 1
16 scrapie affected goats	91	2279	2 to 69

These figures show a relationship between vacuolated nerve cells and scrapie that is obviously highly significant Dr Bosanquet and her colleagues have stated that *scrapie is essentially a myopathy* This may be correct but it does not alter the fact that vacuolated nerve cells occur in the medulla oblongata of many cases of scrapie in a concentration that far exceeds anything that has yet been recognised in any other disease of goats or sheep

With regard to your contributors' scepticism about the experimental transmission of scrapie, I would like to mention some recent experiences with goats

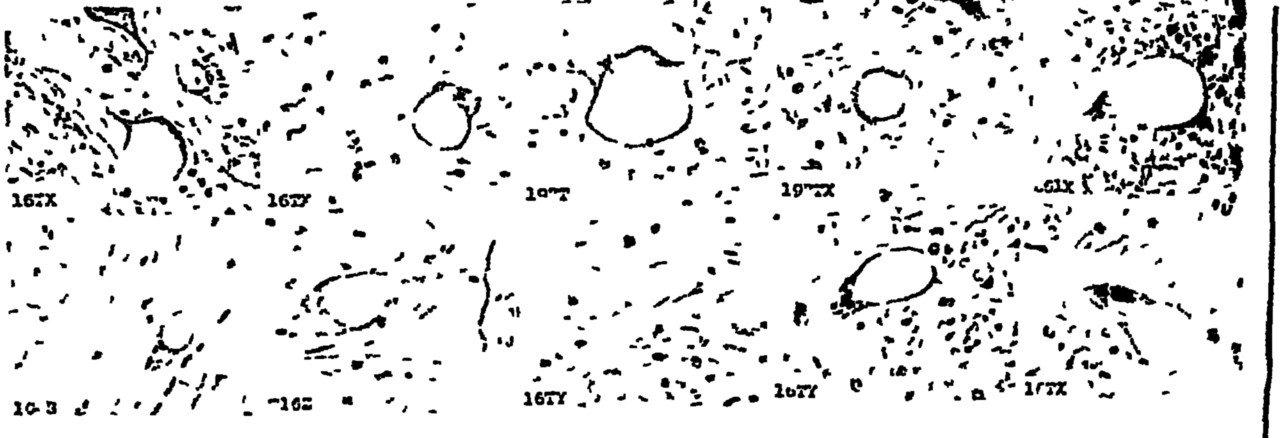
In 1954 I inoculated twelve goats from the Compton flock intracerebrally with 1 0 ml of a 10% brain emulsion from a sheep affected with scrapie All twelve animals developed the disease, the earliest symptoms being noted 15 months *after inoculation I then inoculated ten more goats* with brain emulsion from one of these animals, and to date only of these have developed the disease By contrast over 6 other goats have passed through this flock since 1949 without showing the slightest evidence of scrapie, myopathy, or any other nervous or muscular disability

This type of information has been accumulated over many years by other workers using sheep (notably at Moredun Institute, Edinburgh), and for me it constitutes evidence heavily in favour of scrapie being a disease that can be experimentally transmitted Control inoculation of sheep with brain material from clinically healthy sheep have never produced disease

In conclusion, I would like to say that we await with great interest the results of further researches by Dr

---

1 Holman H H Pattison I H *J comp Path* 1943 53 231



Bosanquet and her colleagues It may be that myopathy is the essential lesion in scrapie, and it is reassuring, therefore, that with such a wealth of natural, experimental, and control material readily available it will not be long before the relationship of myopathy to scrapie is established to the satisfaction of all concerned in the investigation of this odd disease

THE Rh BLOOD-GROUPS

SIR,—Your editorial of July 21 criticises the tentative report of the American Medical Association's Committee on Medicolegal Problems because it recommends that "the C D-E notations for the Rh Hr types be discarded and that, in approved medicolegal reports, unless and until some other convention is agreed on, the original Rh-Hr nomenclature be retained as the sole nomenclature for this blood group system" This editorial is misleading since it contains serious errors of commission and omission, and, instead of citing scientific observations to support its position, it quotes "testimonials" from papers published almost a decade ago, and closes with four lines of poetry from *Ingoldsby Legends* which have no bearing on the scientific issues at stake

The issue of the *Journal of the American Medical Association* which contains the tentative report also contains an editorial requesting comments from workers in the field Since one of the arguments frequently offered by C D-E advocates is that "99% of workers prefer the C-D-E notations," it is noteworthy that approximately half the letters received in response to this request enthusiastically endorsed the position taken by the committee If it were true that C-D-E is preferred by the large majority, it would have been easy to obtain agreement by taking up the matter at the recent meetings of the International Society of Hematology in Boston, and it is significant that this opportunity was not used In fact, one year before the report was prepared by our committee, an effort was made to hold a meeting to discuss Rh Hr nomenclature, and, to avoid the possible charge of bias, a leading advocate of C-D-E was asked to act as chairman But the plans for this meeting were abandoned when Race and Fisher both declined an invitation to participate On the other hand, at a meeting of the International Society of Hematology held in Buffalo six years ago, a committee on Rh Hr nomenclature was formed of which I was not a member This committee introduced a resolution that the C-D-E notations be made international, but the motion was withdrawn when I pointed out that this was a problem to be settled not by vote but by work in the laboratory These facts are not commonly known, and were not mentioned in your inaccurate historical review Interested readers can find a detailed analysis of the scientific background in recent articles[1-3]

You said that Race and Sanger "note that only the C D E notation indicates which antigens and genes are present, and they are convinced that anti C and anti D are more rational names for antibodies than anti rh' and anti Rh_0" This is incorrect since, for example corresponding to the gene symbol r'^w, Fisher and Race use the "chromosome" symbol C^wdeF, which includes the letters d and F for antigens for which no testing sera exist, and at the same time conveniently omits the letter C (rh') for a factor present in agglutinogen rh'^w Yet this assertion and other similar mis statements in Race and Sanger's book have been quoted over and over in the literature[4] Moreover, the symbols C and D are not rational, since by assuming a one to-one correspondence between genes, antigens, and antibodies, no distinction is made between factors, agglutinogens, and genes This has resulted in numerous paradoxes,[5] and in medicolegal problems could cause mistakes which might result in a miscarriage of justice For example, the following represents a *hypothetical* case in terms of the Rh-Hr nomenclature

Blood of	Rh Hr type	
	Phenotype	Possible genotypes
Putative father	Rh_1rh	R^1r, R^1R^0, or R^0r
Mother	rh	rr
Child	Rh_0	R^0R^0 or R^0r

Obviously, the Rh Hr tests do not exclude paternity Yet in terms of the C-D E notations the same case might be reported as follows

Blood of	Most likely genotype
Putative father	CDe/cde
Mother	cde/cde
Child	cDe/cde

Such a report could mislead one into believing that the Rh-Hr tests exclude paternity That this danger is not merely theoretical can be seen from similar errors in published articles, caused by the use of the C-D E notations For example, the diagram of a pedigree in a recent paper[6] shows two women of genotype cDe/cde with children of a genotype CDe/–D–, combinations which would exclude the possibility of maternity!

The main arguments offered nowadays in defence of the C D E notations are that they are easier to "understand" and to teach Significantly, in the 1956 editions of the excellent books by Boyd and Mollison, the tables on the Rh-Hr types list reactions by antisera C, D, E, c, d, and e While such a simple symmetrical scheme is indeed easy to teach, it is unrealistic since it includes the anti d (Hr_0) which has not been found, but omits anti C^w (rh^w) and anti-f (hr) (Incidentally the books of Race and Sanger and of Kabat cite the "discovery" of d as confirmation of the Fisher hypothesis, but in the very next breath confess that the reports in question were almost surely based on faulty observation) Thus, the simplicity of the C D-E notations depends on distortion of scientific facts, whereas a good teacher never finds it necessary to distort in order to achieve simplification Authoritative simplified reviews can be found in many textbooks[7-12]

Certain correspondents who criticised the report insist that the Rh Hr nomenclature be dropped and the C-D-E notations be made international, but at the same time, somewhat inconsistently, urge that the so called "shorthand" symbols be retained These "shorthand" symbols, widely used by Fisher, Race, and other advocates of C D E, are merely minor modifications of the original Rh Hr nomenclature Thus, R_1R_2 is used as

SARCOIDOSIS

SIR,—In your leading article of Dec 29, you state that Nethercott and Strawbridge have presented important indirect evidence of the presence of tubercle bacilli in lesions of sarcoidosis Their evidence rests on the claim to have demonstrated α-ε-diaminopimelic acid (D A P) and mycolic acid in hydrolysates of biopsied tissues Dr Work (Dec 22) has dealt with the significance of D A P , and our observation of the presence of D A P in a scalene lymph node, which histologically appeared to be normal, adds point to her remarks This observation is not unexpected since this type of tissue, in the normal course of events, deals with debris from bacteria, many of which, as Dr Work stressed, contain D A P

Mycolic acid is much more specific to tubercle bacilli than is D A P , and its identification in tissues would be important, but the evidence for its presence is not very convincing

In the first place, although acid fastness could indicate mycolic acid, it is surely not justifiable on the basis of a staining reaction alone, to claim, as Nethercott and Strawbridge[1] do that mycolic acid was *identified* Apart from this, the authors have not specified in any detail the conditions of their acid fast tests, nor have they given any data for normal tissue extracts or for long chain fatty acids other than mycolic Though mycolic acid, either free or in certain of its compounds, is thought to be responsible for the acid fastness of tubercle bacilli, unless the test is carried out under carefully controlled conditions, it is possible to obtain positive results with lipids that do not contain mycolic acid For instance, we have recently tested on filter paper, samples of stearic acid, cholesterol and an extract of normal subcutaneous tissue hydrolysate, staining for 5 minutes with carbol fuchsin and washing for 30 minutes with acid alcohol Stearic acid gave an intense red spot whilst the others were of moderate intensity

The authors erroneously describe their solvent extracted material as "wax" Such substances could not survive prolonged heating with strong acid and their extract would consist predominantly of a mixture of long chain fatty acids derived from the fats of the tissue If mycolic acid were present it would almost certainly form only a very small proportion of the total and it is therefore rather difficult to see how mycolic acid can be distinguished in the infra red spectrum of this mixture, or why this spectrum should be so similar to that of wax C this is very rich in mycolic acid but also contains trehalose, which cannot possibly be present in the tissue extracts Infra red spectra give information regarding the functional groups present (OH NH, C=O &c) —for instance the peaks at 1725 cm^{-1} could correspond to the carbonyl groups of fatty acids It is not at all obvious from the spectra presented that a fatty acid is present which contains 88 carbon atoms—a feature which distinguishes mycolic acid from all other natural fatty acids In the absence of further data the similarity of the spectra tells us that similar functional groups are present in both specimens, which is to be expected since bacterial and animal lipids have many groups in common

It is to be hoped that the authors can clear up these queries Perhaps they have more data and intend to publish their results more fully elsewhere This would be welcome but for the present I think it advisable to accept their evidence for mycolic acid with some reserve

Canadian Red Cross Memorial Hospital
Taplow Maidenhead Berks   R CONSDEN

SIR,—In your leading article there occurs the sentence "D A P has been found in *Corynebacterium diphtheriæ* and *Mycobacterium tuberculosis*, but never in normal mammalian tissue" While this statement is true so far as it goes, it gives an incomplete and slightly misleading impression of the distribution of diaminopimelic acid (D A P) in bacteria and the use to which its occurrence in mammalian tissue could be put in diagnosis

D A P is widely distributed in micro organisms, as has been shown by Work and collaborators,[1 2] and our own work[3 4] indicates that the bulk of it is most probably in the cell wall of those species in which it occurs It is certainly present in the cell wall of species of Bacillus, Nocardia and Streptomyces, as well as in Mycobacterium and Corynebacterium, although absent from almost all gram positive cocci and it has also been found in the cell walls of a few strains of Salmonella, Shigella, Escherichia, and Pseudomonas[5 6]

Furthermore, since the bacterial cell wall is very insoluble, it may well persist for a considerable time in the tissues of a mammalian host A chronic infection involving only a few living organisms at any particular time might perhaps pile up a considerable store of material containing D A P , which could then be detected chromatographically On the other hand, persistence of bacterial cell-wall material in the animal body could well mean that D A P found in hydrolysates of tissues had merely accumulated from saprophytic organisms (for example non-pathogenic diphtheroids) and was not the end result of any pathological process In the latter case the finding of D A P in tissue hydrolysates would be very misleading unless its wide distribution among bacteria was borne in mind

CONGENITAL HYPERTHYROIDISM

SIR,—We were particularly interested in the account by Dr Lewis and Dr Macgregor, of congenital hyperthyroidism (Jan 5) because we have recently had a case almost identical in history and appearances, which was described at an Oxford regional pediatric meeting in December

In our case we decided not to give anti thyroid drugs, which might perhaps be harmful, in what was likely to be a transient condition due to maternal thyrotrophic hormone, and we endeavoured to deal with the child's excessive activity and hunger by steadily increasing the amount and strength of feeds, adding casein hydrolysate For four weeks the weight remained level, then the child began to gain, and the evidences of hyperthyroidism and the thyroid enlargement disappeared The child now seems to be thriving

These severe cases are rare, but there is the interesting possibility, suggested by Coccheri,[7] that the very much commoner syndromes of overactivity with feeding difficulty may sometimes be related to a minor degree of hyperthyroidism in the mother

During the last year of her life she developed a well marked Cushing's syndrome. The records of her case were (as is usual) forwarded after her death to the executive council and are unfortunately not now available to me, but I have a vivid recollection of her. Hypertension (systolic over 200) and glycosuria developed, and she became very obese with a typical moon face. A profuse growth of hair with some pimples appeared on her face. Red striæ were inadvertently not looked for until a late stage in her illness when wasting had started, and they were not then observed.

The association of Cushing's syndrome with carcinoma may be more common than the published records would suggest. Doubtless the late stages of cancer are often observed only by us general practitioners. Confronted with a mystifying condition in these circumstances, we are unlikely to seek further specialist advice, without which we are unlikely to be venturesome enough to publish a record of the case.

Birmingham W. M. CHESNEY

Obituary

WILLIAM GEORGE CLARK

C.B.E., M.B. Glasg., F.R.C.P.E.

Dr. Clark, medical officer of health for Edinburgh from 1938 until 1953, died at his home in the city on Jan. 3 at the age of 68.

He was the son of William Clark, a civil and mining engineer, and he was educated in Glasgow. After graduating in medicine in 1910, he held resident appointments at the Glasgow Royal Infirmary, Belvidere Hospital, Glasgow, and Brook Hospital, London. During the 1914–18 war he served as a temporary surgeon in the Royal Navy. After he was demobilised he became an assistant medical officer at Woolwich Tuberculosis Dispensary. In 1920 he took the D.P.H. and joined the staff of the Glasgow health department, in which he rose to become senior deputy M.O.H. During his years in Glasgow he gained a reputation as an administrator and also gave much time and thought to his special interests of health education and the application of epidemiology to the practical issues of infectious disease. Later he made brilliant use of this experience in the sharp outbreak of smallpox in Edinburgh in 1942.

In 1935 Dr. Clark was appointed deputy to the medical officer of health for Edinburgh, and he succeeded him three years later. He was elected an M.R.C.P.E. in 1939, and became a fellow three years later. His distinguished service was recognised by his appointment as honorary physician to King George VI in 1945. When he retired in 1953 he was appointed C.B.E. in recognition of his organisation of the war-time health and casualty services in Edinburgh.

J. M. M. writes:

George Clark was a well known figure in the public health service of the United Kingdom for many years. He took a keen interest in the Society of Medical Officers of Health, and was elected its president in 1952. In his own domain he pursued a vigorous policy of prevention, and was never afraid of speaking his mind, either on immediate problems or in the wider councils of public health in the country generally. He was also a lively and successful teacher, exercising a great influence on generations of undergraduate and postgraduate students in the university, where he held the post of senior lecturer until his retirement in 1953.

In 1948 he became one of the original members of the Scottish Central Health Services Council, and he gave it his loyal service despite his outspoken criticisms of the Act and its operation. He had strong leanings towards the preventive side, which he felt was somewhat neglected. He was also an active member of the General Nursing Council, and took a great interest in the educational aspect of its work, with his continuing emphasis on prevention.

His many friends will remember him chiefly as a forceful, robust, and genial man. When something was said with which he disagreed, the big eyebrows would go up and he would look like a forbidding fortress. His first sentence in reply would emerge like a rocket. Then the eyebrows came down and he grinned happily. In support of his views, which were often strongly individualistic, he was a bonny fechter, but he never wounded a friendship. A large-hearted man.

Dr. Clark married in 1921 Gladys Catherine, daughter of C. H. Harrison, of Great Yarmouth. She survives him with one son, who is in the government service in Nigeria.

THOMAS ALEXANDER BRITTEN HARRIS

M.D. Melb., F.F.A. R.C.S., D.A.

Dr. Harris, senior anæsthetist and director of the department of anæsthetics at Guy's Hospital, died in London on Dec. 27 at the age of 59.

He was the son of a doctor who was a well-known political figure in Australia, and he graduated M.B. at Melbourne University in 1922. For several years he helped his father in general practice in a small community: this invaluable experience made him a good doctor. He came to this country as an anæsthetist at the West London Hospital. In 1935 he was appointed to the staff of Guy's Hospital, and his enthusiasm and search for knowledge soon made him well known to practically every member of the staff and school: when not teaching anæsthetics, he was picking the brains of the departments of physiology, pharmacology, or biochemistry. He taught anæsthetics in such a way that his students understood the mode of action of the drugs they used and became able to give a simple anæsthetic with confidence and safety. He also joined the staff of St. Peter's Hospital for Stone.

During the late war he served at Tidworth until 1942, when he was posted to India, where he became adviser in anæsthetics to Eastern Command with the rank of lieut.-colonel. One of his duties was to run intensive training-courses, and H. K. A. recalls that he ran them with "energy, conscientiousness, and scrupulous fairness to the candidates."

Whenever Tommy decided (he continues) that a candidate would not make the grade—and it was on his recommendation alone that an officer was or was not posted for anæsthetic duties after attending his course—he nearly always wrote me a personal letter wondering whether or not he was right. But after a month of intensive tuition from Tommy, there were few who did not make the grade and fewer still who subsequently did not prove in practice the soundness of his teaching. In the monthly intervals between courses he constantly toured the forward areas on the Assam and Arakan fronts, staying with the mobile surgical units and casualty clearing stations, watching them at work, and after his return to Calcutta, sending clear, concise, and, practical reports on what could and should be done to improve the anæsthetic service and equipment of these units. His energy was boundless. He wrote such an excellent statement of the case for a monetary grant for technical help in his research on the mode of action of anæsthetic drugs that he miraculously extracted it from G.H.Q. India, in spite of that august body's preoccupation with the war. Much of his book was planned and written in his small, comfortable, and always hospitable flat in Calcutta, where he was never happier than when entertaining his friends and colleagues. Despite his serious demeanour and his quiet and deliberate speech in the pleasant Australian accent which he never lost, Tommy was always gay and full of fun.

In 1948 he was elected F.F.A. R.C.S. In 1951 the first edition of his book *The Mode of Action of Anæsthetics* was published, and at the time of his death he was preparing a second edition. He was also studying the barbiturate antagonists, and he was making an extensive survey of the relationship between the use of muscle relaxants and anæsthetic mortality. For much of the time he worked too hard, and even after a coronary thrombosis had compelled him to rest for two months he refused to content himself with a less strenuous life.

W. S. McC., who in 1935 had faced the Guy's selection committee with Harris, writes:

The comparatively unknown Australian was appointed in open competition with Guy's men: it was a fortunate day for the hospital, for the hospital secured the lifetime devotion of a loyal and dynamic worker. He so identified himself with the hospital that he resented even mild criticism of Guy's and its traditions by an outsider. As an anæsthetist he was superb. Although not an imposing figure—he was short, and had not completely conquered a slight stutter—he conveyed to me and to his other patients a remarkable degree of confidence and assurance. For the surgeons he provided exemplary operating conditions and an atmosphere of tranquillity. In the years to come Tommy will be remembered as a man who had a "shorthand" for CDe/cDE, but when the subscripts are converted into superscripts, as in the symbol R^1R^2 of the Rh Hr nomenclature, the symbol apparently becomes unintelligible (cf pp 204 and 218 of Mollison's new book)

In conclusion it must be pointed out that the A M A report was prepared by a fact-finding committee In discharging its duties, this committee was compelled to exclude all material which it found to be incorrect or to lack experimental basis, so that the charge of bias is inapplicable Readers who consult the references cited here will find that the problem of Rh-Hr nomenclature is dead scientifically The only problem remaining is one of education

remarkable capacity for making friends. He was proud of his friends and valued their affection, but he had the courage to offer criticism and advice if he thought it would help them. Although forthright in his comments, his loyalty was constant.

Dr Harris leaves a widow and four sons. A memorial service was held in Guy's Chapel on Jan. 4.

GODFREY TAUNTON HEBERT
D.M. Oxfd, F.R.C.P.

FROM his appointment as physician in charge of the tuberculosis department at St Thomas's Hospital Dr Hebert retired with some regret in 1948 as the great promise of streptomycin began to show. Happily he lived to see modern chemotherapy make easier the way of his successors.

He was born in 1888, the son of a Kentish parson, and he was *educated at Harrow and Christ Church, Oxford*, where he got a first-class honours in physiology. He qualified from St Thomas's Hospital in 1913, and soon afterwards elected to make his career in tuberculosis. In 1920 he was appointed officer in charge of the Lambeth tuberculosis dispensary in St Thomas's Hospital and to the tuberculosis department of the hospital. He was responsible for the treatment of tuberculosis in a large district in south-west London, and by present-day standards had little help in dealing with a vast number of outpatients. With one assistant tuberculosis officer he was responsible for a large pneumothorax clinic. He was elected to the full staff of St Thomas's Hospital in 1927. During the late war his department suffered badly, but through these trying years he continued his full service, at times in very cramped quarters.

Dr Hebert was, according to the custom of his day, a tuberculosis officer and not a chest physician, but many other conditions passed through his hands for diagnosis. He always warned against woolliness in diagnosis, especially of chest films, and he "took a great delight in pulling his colleagues' legs by giving them tricky X rays." He was a former president of the Tuberculosis Association.

W. M. M. writes:

Dr Hebert's greatest interest was in the problems associated with pulmonary tuberculosis. He played a leading part in the development and acceptance of artificial pneumothorax therapy in England and his death severs another link with this important phase in the treatment of the disease. During the earlier years the interpretation of chest X-ray shadows was an ever-present topic for discussion—the significance of cavitation, the presence of fibrosis, and similar questions required answers which were not easily obtained. He loved such controversies and would delight, with a characteristic nod of his head, slight stutter, and a twinkle in his eye, to argue and tease and so illustrate the points of his teaching. His wide experience was invaluable to his assistants and students. Many house-physicians at St Thomas's served their apprenticeship in practical medicine as clinical assistants in his department. Their knowledge of chest disease and their skill in "needling" owed much to his clear and concise instruction.

In 1919 Dr Hebert married Miss Constance Tatton, who survives him with two daughters. *He died in* hospital in London on Jan. 4.

ERNEST THOMAS GASPEY
M.R.C.S.

Dr Gaspey, formerly medical superintendent of Tehidy Sanatorium, Cornwall, died on Jan. 1 at the age of 68. He should have qualified in Brussels where he was studying medicine when war began in 1914. The invasion of Belgium forced him to come to this country where he qualified in 1916. After the war he took up tuberculosis work and he held posts with the Welsh National Memorial Association and at sanatoriums at Montana and Matlock before he was appointed to Tehidy Sanatorium. C. S. writes: "While Gaspey was in Switzerland he met Spahlinger and observed his treatment of tuberculosis, and Gaspey's account of this was an interesting story. He was superintendent of Tehidy Sanatorium for many years until he retired three years ago. He had a remarkable faculty of remembering and being remembered by his ex-patients and there were few villages in Cornwall where he was not recognised and welcomed by someone for whom he had cared."

JAMES ROY OWEN
M.R.C.P.

Dr James Owen, senior honorary physician to the skin department of the Royal Northern Hospital, London, died on Dec. 28. He qualified from the Birmingham Medical School in 1920 and held house-appointments at the Queen's Hospital, Birmingham. Later he became first assistant to medical outpatients at the London Hospital and medical registrar at the Royal Cancer Hospital and the National Temperance Hospital. He took the M.R.C.P. in 1937, and after setting up in consultant practice joined the staff of the Hospital for Diseases of the Skin, Blackfriars. During the late war he was in charge of the medical division of an R.A.M.C. general hospital and he also acted as a blood-transfusion officer in the Emergency Medical Service. Besides his appointment at the Royal Northern, he was physician in charge of the skin department at Ashford County Hospital, and honorary physician for diseases of the skin at Hampstead General Hospital, Victoria Hospital for Children, and Queen Elizabeth Hospital for Children.

H. T. H. W. writes:

Those who knew James Owen in former years will remember him as a man of immaculate appearance and debonair charm. He had a passion for adventure and his past activities ranged from jumping by parachute to underwater exploration, with this was coupled a magnificent disregard for the trivialities of life. His essential kindliness endeared him to colleagues, nurses, and patients while his easy wit made him an excellent companion.

HERBERT FOWLIE
M.B. Aberd.

Dr Fowlie, who died at Aberdeen on Christmas Day at the age of 49, graduated M.B. at Aberdeen University in 1930 and, after house-appointments at Carlisle and experience of general practice in Appleby, settled in practice in that city in 1940.

A colleague writes:

By heredity and environment Hebbie Fowlie should have been a farmer, but he turned to medicine, *saying*, as he often did, that he "hadna the brains for farming." He soon became one of the busiest, best known, and best loved family doctors in Aberdeen. He was of great humanity and transparent honesty, of infinite patience when patience was needful, but of blistering *impatience* with *incompetence* or dishonesty. He made friends of all whom he met in his practice, on the golf course, or on his beloved shooting and fishing excursions. He was a wise and considerate colleague and the family doctor of a number of medical households including my own; he *paid us a visit only a few hours before his death*, and he left us all laughing, for his gaiety was infectious and wherever he went he left laughter and lightened hearts behind him. We, who were his patients, can say with pride and gratitude—"He was our doctor, aye he left us cheered."

Dr Fowlie leaves a widow, a daughter, and two sons.

Appointments

DOODY, P. J., M.B. N.U.I., D.I.H.: M.O., Wimbledon.
FRANCIS, A. J., M.D. Lond.: assistant pathologist (S.H.M.O.), St Peter's, St Paul's, and St Philip's Hospitals, London.
GRIFFITHS, J. A., M.D. Sheff., F.F.A. R.C.S., D.A.: consultant anæsthetist, United Sheffield Hospitals.
HALDANE, J. D., M.B. Edin., M.R.C.P.E., D.P.M.: deputy physician superintendent, Fife mental hospitals.
HUDSON, T. G., M.B. Belf., D.A.: assistant anæsthetist (S.H.M.O.) based on the Inverness hospitals.
SCOTT, O. L. S., M.B. Camb., M.R.C.P.: part-time consultant dermatologist, Charing Cross Hospital, London.

Colonial Appointments

BUCHANAN, G., F.R.C.S.E.: surgeon specialist, Western Nigeria.
EVANS, A. J., M.B. Lond., D.A.: senior specialist, Western Nigeria.
GRAHAM, J. L. T., L.R.C.P.E.: M.O., Northern Nigeria.
HAROBIWITS, A., M.B. Camb.: senior M.O., Kenya.
HAY, J. K., M.B. Aberd., D.I.H., D.T.M. & H.: senior M.O., sleeping sickness service, Northern Nigeria.
KALADIA, K. K., M.B. Bombay, D.T.M. & H.: M.O., Western Nigeria.
[illegible], I. A., M.R.C.S., D.I.H., D.D.M.S., Mauritius.
NUGENT, D. A. W., M.B. Madras, D.I.H., D.T.M. & H.: specialist malariologist, ministry of health, Gold Coast.
NWOKOLO, C., M.R.C.P.E.: specialist (physician), Eastern Nigeria.
ONWUMERE, R. J., M.R.C.S., D.O.: specialist (ophthalmology), Eastern Nigeria.
LARKINS, C. H., M.D., D.I.H.: senior radiologist, Jamaica.

The Birmingham Regional Hospital Board inform us that Dr W. G. A. Bigg, whose appointment as assistant psychiatrist to Shrewsbury group of hospitals we announced in our issue of Dec. 8, later withdrew from the appointment.

Notes and News

PATHOLOGICAL SPECIMENS BY POST

THE Post Office has expressed concern at the ineffective packing or sealing of some pathological specimens sent through the post If the material is infected or toxic, this may be hazardous for Post-Office workers, and, through contamination of other mail, for the general public Sometimes a patient is given a receptacle to send a specimen, but not told how to pack it, written instructions should always be given with containers The Post Office's instructions for packing such deleterious substances, which may be sent by letter post but not by parcel post, are as follows

> Any such liquid or substance must be enclosed in a receptacle, hermetically sealed or otherwise securely closed and this receptacle must itself be placed in a strong wooden or metal case (or other case which has been approved by the Post Office) in such a way that it cannot shift about, and with a sufficient quantity of some absorbent material (such as sawdust or cotton wool) so packed about the receptacle as absolutely to prevent any possible leakage from the package in the event of damage to the receptacle The packet so made up must be conspicuously marked "Fragile with Care" and bear the words "Pathological Specimen."

MEDICAL MEMBERSHIP OF HOSPITAL AUTHORITIES

THE Minister of Health has accepted the recommendation of the Guillebaud Committee that no more than a quarter of the members of regional hospital boards should be doctors In a circular to hospital authorities (H M [56] 111) he explains that in future he will observe this principle in appointing regional hospital boards, and asks that the boards shall do the same when appointing hospital management committees The Guillebaud Committee made no recommendation about the membership of boards of governors, and, as university nominees (who may be doctors) sit on these boards as well as representatives of the hospital medical staff, the Minister thinks it inappropriate to limit the proportion of medical members on these boards to a quarter of the total membership But he has asked R H B S when nominating their members to boards of governors to bear in mind "the desirability of securing a reasonable balance of lay representation"

MEDICAL CARE FOR AMERICAN SERVICEMEN'S DEPENDENTS

THE dependents of American Servicemen who live on or near military posts have by tradition been allowed to share the medical services available to their husbands and fathers In practice this has come to mean that no medical care is provided for those who probably need it most—the families of men serving overseas The Dependents Medical Act was passed last year by Congress to correct this anomaly When the Act was under discussion the Armed Services committees said that the Services could no longer compete with private industry for talented men, because industry offered so much more in benefits such as health insurance Under the Act the new scheme, which is popularly known as Medicare, came into force last month (*New York Times*, Dec 25, 1956) It provides hospital and medical care for the 800,000 dependents of Servicemen who do not live at military posts Hospital fees are being arranged through an insurance company, which is handling the business without profit, and through the Blue Cross a non profit organisation In all save two States doctors' fees will be handled by State medical associations Where a Service wife prefers to go to a civilian hospital the government will usually pay a substantial part of the costs

COUNTY CHARITIES

THE Welfare State has not wiped out the need for private charity but it has altered its purpose The widow can now rely on getting her dole from the post office, the orphan is sure of his schooling but both will still be grateful for some extra help—perhaps to buy more coal at Christmas, perhaps to eke out a scholarship which leaves little over for clothes or books Through the centuries almost every village has acquired some local trusts With the changing value of money some are today worth much less than their donors intended Others by fortunate investments have greatly increased their incomes A register of all this scattered well doing would be useful to many people and Dr I H C Clarke by listing *Charities in Kesteven* has provided what is thought to be the first county list Other medical officers of health may follow his example, for as he points out in his introduction, charities can be regarded as an instrument for the betterment of public health" The present state of honest but ineffective nescience is well shown by the last entry on his list under the heading "Unknown Charity"

> An income of 10*s* 8*d* p a is paid by the Charity Commissioners into the Midland Bank, where it is accumulating the balance being now a little over £9 Nothing appears to be known locally as to the origin or purpose of the Charity

By the end of 1957 surely some part of Kesteven will have put that £9 to good use

NEW MULTILINGUAL JOURNAL

Living Conditions and Health, a new quarterly journal sponsored by the World Congress of Doctors for the Study of Present day Living Conditions, appears in identical form in English, Chinese, French, German, Russian, and Spanish The English edition may be had from Dr A Ryle, the Caversham Centre, 25, Caversham Road, London, N W 5 (annual subscription 26*s*, single copies 7*s* 6*d*)

Royal College of Physicians of London

Dr D D Reid will give the Milroy lectures on Tuesday and Thursday, Feb 5 and 7, at 5 P M, at the college, Pall Mall East S W 1 He will speak on Environmental Factors in Respiratory Disease

Royal College of Surgeons of England

The Hunterian festival dinner will be held in the college on Thursday, Feb 14 The guests will include the Archbishop of Canterbury, the Lord Chancellor, the Minister of Education, and the Secretary of State for War Fellows and members may obtain tickets (£2 10*s*) from Mr W F Davis, deputy secretary of the college, Lincoln's Inn Fields, London, W C 2

International Congress of Therapeutics

This congress, which is sponsored by the International Union of Therapeutics, will be held at Utrecht from June 4 to 6 Further particulars may be had from the general secretary, Vondellaan 6, Utrecht, Holland

British Association of Plastic Surgeons

At a meeting of this association on Dec 14, with Mr Wilfred Hynes in the chair, Mr R P Osborne was elected president-elect and treasurer, and Mr C R McLaughlin hon secretary

Royal Appointment

Surgeon Captain Reginald Wear, R N V R, has been appointed an honorary physician to the Queen in succession to Surgeon Captain H M Willoughby

World Federation for Mental Health

Dr Margaret Mead, president of the federation, will give an address at County Hall, London, S E 1, on Friday, Feb 8, at 5 45 P M, on Mental Health in a Changing World Tickets (2*s* 6*d*) may be had from the National Association for Mental Health, 39, Queen Anne Street, W 1

Chronic Rheumatic Diseases

A course on this subject with lectures, ward rounds, and practical demonstrations, is being held at the rheumatism unit of St Stephen's Hospital, Fulham Road, London S W 10 on Saturday and Sunday, March 9 and 10 Further particulars can be had from the secretary, Fellowship of Postgraduate Medicine 60, Portland Place, W 1

Education of the Public regarding Cancer

The Central Council for Health Education is holding a conference on this subject at B M A House, London, W C 1 on Thursday, Jan 24, at 11 15 A M The conference is intended for chairmen of health committees, medical officers of health and their staff, members of hospital staffs, and others interested The speakers will include Mr R W Raven and Dr John Burton Further particulars may be had from the council Tavistock House North Tavistock Square, London W C 1

World Medical Association

The World Medical Association, founded in 1947, has as its first object "to promote closer ties among the national medical organisations and among the doctors of the world by personal contact and by all other means available" A British supporting group is to be formed, to stimulate interest in and provide financial support for, the association The inaugural meeting will be held at British Medical Association House Tavistock Square, London W C 1, at 3 30 P M on Tuesday Jan 29

British Overseas Airways Corporation

Dr Kenneth Bergin B O A C 's medical superintendent, Air Services, has been appointed to the post of chief medical officer to the corporation

Nuffield Dental Fellowships

One of the aims of these fellowships is to enable graduates in medicine and science to qualify themselves to undertake teaching and research on dental health and disease Further particulars will be found in our advertisement columns

Ageing and Old Age

A symposium on this subject, organised by the department of studies in psychological medicine of the University of Liverpool will be held on Saturday, March 23 The speakers will be Dr A Heron, Prof A B Semple, and Prof Martin Roth Further particulars can be had from Dr H Jarvie, 77 Bedford Street South, Liverpool 7

Royal Society of Health

The annual congress of this society is to be held at Folkestone from April 30 to May 3 For the first time it will include a section on hospitals over which Lord Inman chairman of Charing Cross Hospital, will preside The tercentenary of the death of William Harvey coincides with the congress, and Sir Arthur MacNalty, F R C P , will give a lecture on Harvey's influence on public health Further particulars may be had from the secretary of the society 90, Buckingham Palace Road, London, S W 1

Volunteers for Research on Common Cold

The Common Cold Research Unit at Harvard Hospital, Salisbury is starting its eleventh year with an appeal for more volunteers especially for the next two 10 day sessions, starting on Jan 15 and Jan 29 From now until the end of March some 100 volunteers are wanted, and there will be vacancies during the rest of the year for 400 to 500 Comfortable living quarters are provided, fares to and from Salisbury are paid up to a maximum of £3, and 3*s* a day pocket money is allowed Volunteers should be between 18 and 45 years of age and in normal health Further particulars may be had from the medical superintendent of the hospital

Committee on Public Health Engineering

The Institute of Sewage Purification the Institution of Municipal Engineers the Institution of Public Health Engineers the Institution of Water Engineers, the Royal Society of Health the Royal Institute of Public Health and Hygiene the Sanitary Inspectors' Association, and the Society of Medical Officers of Health have agreed to set up a coordinating committee to deal with problems in this field Sir Allen Daley, F R C P is the chairman and the secretary is Mr P Arthur Wells M SC (Royal Society of Health, 90, Buckingham Palace Road London, S W 1)

Medical Research Council

The council invite applications for the following fellowships for 1957–58

Rockefeller Travelling Fellowships —These fellowships are intended for graduates resident in this country who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad before taking up appointments for higher teaching or research in the United Kingdom

Dorothy Temple Cross Fellowships in Tuberculosis —These fellowships offer special opportunities for study or research to British doctors who intend to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis The fellowships will as a rule be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom

Alexander Pigott Wernher Fellowships in Ophthalmology and Otology —These fellowships are intended for doctors who are likely to profit by a period of work in ophthalmology or otology at a centre abroad before taking up positions for higher teaching and research in these branches of medical science The awards will normally be tenable for one year

All the fellowships provide for the payment of a maintenance allowance at the rate of £650 per annum for a single fellow or £900 per annum for a married fellow ($2700 and $3900 respectively if the fellowship is held in the United States) Allowances are made for travelling and other approved expenses Forms of application for these fellowships may be had from the secretary of the council 38 Old Queen Street London S W 1 with whom applications must be lodged by March 15 (March 31 for the Pigott Wernher fellowships)

CEREBRAL ABSCESS IN CYANOTIC CONGENITAL HEART-DISEASE

MAURICE CAMPBELL
M A, D M Oxfd, F R C P

PHYSICIAN IN CHARGE OF THE CARDIAC DEPARTMENT, GUY'S HOSPITAL, PHYSICIAN, INSTITUTE OF CARDIOLOGY, LONDON

IN 1814, Farre described a cyanotic boy, aged 9, with Fallot's tetralogy and a brain abscess As early as 1880, Ballet thought there was an association between these two conditions and wrote " En résumé, coexistence d'une malformation du cœur et d'un absces du cerveau, tel est le trait d'union qui rapproche les unes des autres les six observations précédentes Faut il voir dans cette coexistence une relation étiologique entre les deux ordres de lésions ? " He thought so, because there was no other reason such as trauma or infection of the ear or nasal sinuses to explain the presence of the cerebral abscess

Ballet was describing the case of a large fronto parietal abscess in a boy of 15 where the two atria drained into the left ventricle and the small right ventricle could be reached only through a ventricular septal defect He found reports of five other cases, all of which had defects of the atrial or ventricular septa, sometimes with an overriding aorta so that, as he pointed out, the venous blood could easily become mixed with the arterial blood He concluded " Aussi bien pensons nous qu'on ne saurait expliquer par une pure coincidence le fait de 6 cas de malformations du cœur s'accompagnant d'absces du cerveau , que ce chiffre a son importance qui merite de fixer l'attention, et qu'il est logique d'admettre une relation étiologique entre les lesions précedentes "

As late as 1945, Robbins, reporting three cases among patients with Fallot's tetralogy, could find only twenty-three others, and only three where surgical treatment had been attempted Newton (1956), reporting seven cases from Birmingham, brought this total up to seventy-nine only Hence the following fifteen cases seem worth reporting

The Present Series

During the past 10 years, among our patients with cyanotic congenital heart disease (about eight hundred) we have seen fourteen with an abscess of the brain, of whom nine have died and five have recovered after surgical treatment We are including a fifteenth patient who after a sudden loss of consciousness and a right hemiplegia recovered with penicillin treatment only, because even if the diagnosis of brain abscess was incorrect the alternative of an infected embolism may help in understanding the cause of this association I saw them all for their heart condition but only some of them when they had a brain abscess This number of cases leaves little doubt that cerebral abscess occurs more often in patients with cyanotic congenital heart disease than in others A sixteenth acyanotic patient is dis ussed

These fifteen patients (ten male and five female) were between 3 and 25 years of age, and the age incidence was roughly the same as in our total number of patients In general, there is no difference in the sex-incidence

The Condition of the Heart

All the fifteen patients had central cyanosis with a right to left shunt (see tables I and II) eleven had Fallot's tetralogy , two had all the features of Fallot's tetralogy except that they had pulmonary atresia instead of stenosis, and two had an increased blood flow to the lungs and were diagnosed as having transposition of the aorta and pulmonary trunk Necropsy confirmed partial transposition in the last two, for in case 9 the aorta arose entirely from the right ventricle and in case 8 the pulmonary trunk arose from a rudimentary chamber of the left ventricle and there was a single atrium and a single atrio-ventricular valve One of the patients with Fallot's tetralogy had also situs inversus (case 15) and another had enough dextro-rotation to simulate dextrocardia (case 7) No patient had any evidence of subacute bacterial endocarditis

The Brain Abscess

Brain abscesses of all types are most often solitary and most often in the temporal lobe In abscesses associated with cyanotic heart-disease the former is true , but there is no high incidence in the temporal lobe, for this is due to the frequent association with middle ear disease

In our series, eleven patients had solitary abscesses One (case 3) had two abscesses in the temporal lobe and two others (cases 2 and 4) had multiple abscesses

The abscesses were widely scattered in two they were multiple and on both sides, in 4 on the right, and in 8 on the left side In the seventy nine cases collected by Newton (1956) they were equally distributed on the right and left sides and no lobe was affected much more frequently than the others The sites of the abscesses in our patients, excluding the two where they were multiple, were distributed as follows —3 frontal, 2 fronto parietal, 1 parietal, 1 fronto temporal, 2 temporal, and 3 occipital In most general series of brain abscesses apart from those with morbus cœruleus the parietal and occipital lobes are relatively uncommon sites

We are not discussing the symptomatology or treatment at length It may, however, be of interest to mention the more dramatic symptoms, for often these came with little warning and the period of headaches with increasing

TABLE I—PATIENTS WHO DIED WITH A CEREBRAL ABSCESS

Case	Sex and age at death	Condition of heart	Cerebral findings
1	F, 25	Fallot's tetralogy with severe infundibular and some valvular stenosis	Large abscess in posterior part of lt occipital lobe that had ruptured into lt lateral ventricle
2	M, 15	Fallot's tetralogy with low infundibular stenosis and small atrial septal defect	Multiple abscesses, lt temporal (15 mm diam), rt parietal (7 mm diam) and lt occipital (15 mm diam) tuberculous basal leptomeningitis
3	M, 12	Fallot's tetralogy with infundibular stenosis	Two large rt temporal lobe abscesses one of which had ruptured into 3rd ventricle
4	M, 6	Fallot s tetralogy with infundibular stenosis	Multiple abscesses Lt frontal, lt temporo-parietal rt frontal, rt fronto parietal rt temporo parietal (2) and rt cerebellar
5	M, 6	Fallot's tetralogy Successful subclavian pulmonary anastomosis 26 months before	Rt parietal lobe abscess Died after operation for abscess
6	M, 4	Atresia of a bicuspid pulmonary valve with other features of Fallot's tetralogy	Large abscess occupying most of lt frontal lobe, older postero medially and more recent antero-laterally
7	M, 3	Fallot's tetralogy with valvular stenosis aorta well over to right , dextro rotation simulating dextrocardia	Rt frontal abscess (2 cm diam) that had ruptured into rt and 3rd ventricles extensive basal meningitis
8	F 8	Transposition clinically at necropsy, single atrium, single atrio ventricular valve, pulmonary trunk from infundibular" chamber of left ventricle	Lt fronto temporal multilocular abscess 5 × 6 × 4 cm
9	M 6	Transposition clinically, at necropsy, aorta and pulmonary trunk both from right ventricle Large ventricular septal defect	Large solitary abscess (8 cm diam) in lt fronto-parietal lobe

TABLE II—PATIENTS WHO RECOVERED FROM A CEREBRAL ABSCESS *

Case	Sex and age (years)		Condition of heart	Cerebral findings
10	M	1	Fallot's tetralogy Some improvement after subclavian pulmonary anastomosis 3 months before	Rt posterior frontal region abscess Recovery after repeated aspiration
11	M	19	Fallot's tetralogy Successful subclavian pulmonary anastomosis 27 months before	Lt temporal lobe abscess Recovery after aspiration and operation
12	F	10	Fallot's tetralogy Successful subclavian pulmonary anastomosis 33 months before	Lt occipital lobe abscess Recovery after aspiration and operation
13	F	5	Fallot's tetralogy Successful subclavian pulmonary anastomosis 4 months before	Lt fronto parietal abscess Recovery after aspiration and operation
14	M	7	Pulmonary atresia with other features of Fallot's tetralogy	Lt occipital region abscess Recovery after repeated aspiration
15	F	12	Fallot's tetralogy and situs inversus Cardiac catheterisation 6 weeks before	Loss of consciousness with rt hemiplegia Cerebral abscess from septic embolism diagnosed recovery with penicillin only, but residual hemiplegia

* An additional patient has been seen since A girl aged 7 who had Fallot's tetralogy with stenosis that was thought to be infundibular seemed too well to advise operation But 18 months later she was admitted to hospital with meningeal signs cerebral irritation and papilloedema The diagnosis of a cerebral abscess in the left parietal region has been confirmed and she is being treated surgically

drowsiness and irritability—a period that is perhaps most characteristic of brain abscess secondary to infection from the middle ear or sinuses—was often short or not sufficiently noticeable to be recorded Only one patient, the boy with multiple abscesses, had a long pyrexial period and had been treated as having bacterial endocarditis before the correct diagnosis was made after his admission to Guy's Hospital necropsy confirmed the absence of bacterial endocarditis (case 4)

One patient had fits followed by a left hemiplegia (case 10), one had a right hemiplegia followed by fits (case 8), and another some clumsiness of the right hand followed by two Jacksonian fits (case 13) Three of them (cases 11, 12, and 14) and a fourth patient whose patent ductus arteriosus had been closed 28 months before (case 16) had homonymous hemianopia, two with abscesses in the occipital and two with abscesses in the temporal lobe In one the diagnosis was not made till the abscess had ruptured into the lateral ventricle (case 1)

Treatment

In several of the nine who died the abscess had been aspirated and one (case 5) had an open operation Of the six who recovered two had only repeated aspiration and antibiotics (cases 10 and 14) and three had an open operation as well (cases 11, 12, and 13) Only one—the unproved case 15—recovered with antibiotics only and she was left with persistent hemiplegia The other five made good recoveries though one (case 11) seems to have lost the exceptional energy and perseverance that he had shown since his Blalock operation two years earlier and another (case 12) had some residual organic symptoms in the right arm with a hysterical overlay due to psychological problems at home Three of the cases reported by Newton (1956) recovered after surgical treatment

Relationship to the Cardiac Operation

Of the nine patients who died, only one (case 5) had undergone an operation for his heart—a most successful subclavian pulmonary anastomosis 26 months before On the other hand four of the six who recovered from the brain abscess had undergone operations for the heart, with a good result in all but one, who was only somewhat improved No doubt they were under more regular observation and were perhaps more ready to seek advice at an early stage, but the symptoms that drew attention to the abscess were often so dramatic that this cannot have been of major importance and their improved condition after the heart operation must have helped in the recovery after the cerebral operation The other two who recovered were being considered for operation one had undergone angiocardiography 11 months before (case 14) and the other cardiac catheterisation 6 weeks before (case 15)

In this last case—the only one we have included when it was uncertain whether she had a brain abscess or an infected embolism, and where she recovered with antibiotics only—it seems probable that catheterisation was the indirect cause In two others (cases 10 and 13) the abscess was diagnosed 3 and 4 months after the operation for the heart and allowing for the time that an abscess may take to develop it seems probable that the operation was the indirect cause In the others, however, the abscess was diagnosed 26, 27, and 33 months after the operation and the patients had been in good health and greatly improved, so we think it unlikely that there was any connection (cases 5, 11, and 12) In the seven cases reported by Newton (1956) the abscess developed after a subclavian pulmonary anastomosis in two and after pulmonary valvotomy in a third

Possible Infections Elsewhere

In general, cerebral abscess arises from extension of infection (60–70%), especially from the ears, or through the blood stream Hæmatogenous abscesses may arise from bacterial endocarditis or other forms of septicæmia but most often from chronic suppuration in the chest especially from bronchiectasis and pulmonary abscess (25% of cases), but in about 10% they appear to arise from a source of infection that cannot be found or has cleared up in patients with morbus cœruleus, however, this last seems to be the common type

Most of our patients were free from signs of infection elsewhere None of them had bacterial endocarditis and none had any recognised chronic suppuration in the lungs None had clear evidence that the abscess was due to disease of the middle ear, though in one this was probable and in a second possible Thus in case 3 with two large abscesses in the temporal lobe, there was pus in the right mastoid but the dura was normal In case 1 there was a left otitis media, but the abscess was in the posterior part of the left occipital lobe and there appeared to be no connection In case 4, with multiple abscesses, there had been a right otitis media two years before, but nothing else was found

Although none of these patients had a cerebral abscess that was certainly attributable to middle ear disease we have seen a boy, aged 7 who has had a successful subclavian-pulmonary anastomosis for Fallot's tetralogy, and had made a good recovery after an operation 5 years before for a pneumococcal brain abscess that had followed directly on otitis media A boy, aged 4, with transposition of the aorta and pulmonary trunk and a ventricular septal defect died with a large abscess in the right temporal lobe following right otitis media A girl aged 1 year, with Fallot's tetralogy, had bilateral otitis media and died with lateral sinus thrombosis of some standing and with recent thrombosis of the superior sagittal sinus and other cerebral veins

Apart from those with proved cerebral abscesses, one other patient was suspected of this A girl, aged 9, with Fallot's tetralogy, developed symptoms 28 months after her Blalock operation, but was thought by Dr. McArdle to have cortical thrombophlebitis rather than an abscess she made an almost complete recovery with penicillin Untreated venous thrombosis of this type might, however, be a source of a subsequent abscess At least two other patients have died with meningitis during this same period, but neither had a necropsy and neither was thought to have a brain abscess In a boy, aged 11, with tricuspid atresia, the meningitis was thought to be tuberculous but the evidence was doubtful, and in a boy aged 11, probably with Fallot's tetralogy, it was meningococcal

Bacteriology

Little useful information can be gained from the bacteriology of the abscesses, for the notes are not very complete and represent the work of several different pathologists

Gram positive cocci were found in cases 3, 10, 12, and 14 In cases 5 and 16 there were non hæmolytic streptococci, and in the former they appeared to be aerobic and facultatively anaerobic Anaerobic streptococci were grown from the abscess at necropsy in cases 7 and 9 A coagulase positive staphylococcus was grown from the abscess at necropsy in case 8, and *Staphylococcus albus* under the same circumstances in case 1 In case 10 there was an aerobic actinomycete, and though this may seem unlikely it was isolated on culture from pus obtained at three separate aspirations In case 2 the abscesses were tuberculous In the twenty two cases of Newton (1956) where cultures were positive, the organisms were very varied and no one type predominated

Discussion

This series of cases and the number that have been reported in the past few years leave little doubt that Ballet's suggestion is correct and that cerebral abscess occurs more frequently in patients with cyanotic congenital heart-disease than in others Hanna (1941), Robbins (1945) and Gates et al (1947) found that there was a brain abscess in about 5% of all deaths of patients with congenital heart disease In our experience of patients with cyanotic congenital heart disease brain abscess is a greater hazard than bacterial endocarditis, though Gates et al (1947) found brain abscess in 4% and bacterial endocarditis in 7% We cannot recollect seeing any patient with acquired heart-disease, and we have seen only one with acyanotic congenital heart-disease, who has subsequently developed a cerebral abscess

In the seventy-nine cases of this association collected by Newton (1956) there was known to be a veno arterial shunt in at least 85%, an absence of any obvious primary infection in 70% and a distribution that did not show the usual predilection for the temporal lobe In the series of Maronde (1950) most of them had Fallot's tetralogy or related conditions, but several had ventricular septal defects only, where presumably the rising pressure on the right side had reversed the shunt In our experience fifteen of the sixteen patients have had a right-to-left shunt

In a 10 year series of necropsies Maronde (1950) found that 10% of all the patients with cerebral abscess had congenital heart disease In the Birmingham series of hæmatogenous brain abscesses Newton (1956) found that 10% had congenital heart disease, while in the general population he calculated that this was present in less than 0 1%

Of sixty-nine hæmatogenous brain abscesses at Birmingham (Newton 1956) and a hundred and four at the Mayo Clinic (Gates et al 1950) 45% were associated with lung infections and 10% with bacterial endocarditis and among these 55% only one had congenital heart-disease on the other hand, congenital heart disease was present in five of the forty eight with other primary infections and in four of the twenty seven with no known primary infection

This association between brain abscess and cyanotic congenital heart-disease seems well established and it is therefore interesting to discuss the reason

Bacteræmia and the Right to left Shunt

At first without much reflection I thought it could be explained by the fact that the right-to left shunt would allow bacteria present in the blood to reach the brain without passage through the lungs this assumes that the brain is less capable of dealing with them, though the action of the lungs in filtering off bacteria is now less generally accepted than it was Indeed, if this were an effective mechanism it would be difficult to explain why bicuspid aortic valves are unusually prone to develop bacterial endocarditis from chance bacteræmia (Osler 1886, 11 5% of all bicuspid aortic valves, Wauchope 1928) for this happens as a rule when there is no right-to left shunt

Furthermore, it is difficult to picture bacteria becoming lodged at any site, for they should be able to pass through the capillaries readily except perhaps in the case of coagulase positive staphylococci, which might collect and form an obstruction De Navasquez (1950) found that the intravenous injection of coagulase positive staphylococci regularly produced pyelonephritis in rabbits while several other organisms were unable to do so it is interesting that at least one of our patients (case 8) had such staphylococci in the brain abscess Also it has been found experimentally that it is difficult to produce cerebral abscess by the injection of bacteria into the blood-stream, and that local trauma or injury to the brain is generally necessary

It seems, therefore, that, in addition to the bacteria there must be some local factor, such as a thrombus or an embolus, leading to slowing of the capillary flow, but generally there is no evidence of a primary thrombus elsewhere

Paradoxical Embolism

Abbott et al (1923) thought that cerebral complications such as abscess or infarction were frequent in patients with congenital septal defects, and that these were generally embolic from a focus in the venous system Paradoxical embolism was reviewed by Thompson and Evans (1930) who gave some striking illustrations but had not much to say about cases where the right-to left shunt was a normal feature They thought that the rise of pressure on the right side of the heart following large or repeated pulmonary emboli was the main cause of a later embolism passing through a foramen ovale that could be forced open by the rise of pressure They also discussed this in relation to brain abscesses of a hundred and ninety-five cases there were twenty-two where the infection was thought to be blood-borne but here it did not seem to make much difference whether the foramen ovale was closed or not, and in more than half of them there were abscesses in the lungs

Classically paradoxical or crossed embolism is related to a patent foramen ovale or sometimes an atrial septal defect though, as Brown (1939) points out it also occurs with a right to left shunt and an overriding aorta, and may explain many cases of cerebral abscess The main argument against this is the absence of signs of a thrombosis from which the embolism may have come Such an infected embolism was suggested as the cause in our cases 15 and 16, but no primary thrombosis was recognised Nor has anyone suggested that systemic emboli elsewhere occur with unusual frequency in patients with morbus cœruleus This difficulty is not confined to cases of congenital heart disease and necropsy may show that a suspected thrombosis was in fact an embolism from an unrecognised thrombosis elsewhere

Emboli from the Lungs

An alternative explanation that discards any direct influence of the right to left shunt might be that the abscesses were due to emboli from the lungs for in these cyanotic cases there is generally a poor pulmonary blood flow and perhaps some tendency to pulmonary thrombosis The cases that follow quickly on surgical treatment might seem to support this for (especially after the early operations, where an undue proportion of these abscesses occurred) there were often some postoperative pulmonary complications, but the patients who later developed brain abscess showed no special incidence of these Even more important, necropsy has not shown any pathological changes in the lungs to support this explanation, either in our cases, or, so far as we know, in other reported cases In the column "primary focus" dealing with the seventy-nine reported cases, Newton (1956) included bronchitis three times but this was the only mention of any disease of the lung further, in seventy seven cases of hæmatogenous brain abscess (quoted in the Birmingham and Mayo Clinic series) that followed bronchiectasis, lung abscess, or empyema, there was not a single example of congenital heart disease

Secondary Infection of a Cerebral Thrombosis

Finally, in considering this series of cases, another explanation has come to seem increasingly likely—that the abscess is due to secondary infection of a cerebral thrombus This does not discard the concept of the importance of the right to-left shunt, for patients with such a shunt have anoxia and polycythæmia, often of extreme degree, and are therefore specially prone to cerebral thrombosis

Peacock (1866) thought that cerebral disturbance, resulting from the defective aeration of the blood, was one of the two most common causes of death in these patients Cerebral disturbance is still common, and is generally due to anoxæmia alone, but often, as Taussig (1947) has emphasised, there is also a cerebral thrombosis Berthrong and Sabistan (1951) found twenty-five examples of cerebral softening, ten with recent infarction, six with older changes, and nine with both, among a hundred and thirty-five necropsies of patients with cyanotic congenital heart disease These cerebral thrombi are generally arterial but one case of thrombophlebitis has been mentioned, and Barnett and Hyland (1953) have reported unsuspected thrombosis in the dural sinuses and cerebral veins in cases of heart failure, which might occur also in the presence of anoxæmia and polycythæmia

We have seen many examples of major arterial thrombosis three early patients developed hemiplegia just after subclavian-pulmonary anastomosis, and in several others this had happened earlier These large thrombi are not often, so far as we know, followed by infection or abscess, but if there are large thrombi there are likely to be smaller ones that might provide a damaged area where bacteria could settle and produce an abscess

Such damaged areas may also be the cause of epileptic fits, and this should be considered when patients are seen with epilepsy and morbus cœruleus Baker and Finnegan (1957) have emphasised that damaged areas in the brain, following embolism, are an important cause of epilepsy in patients with mitral stenosis

Secondary infection of a vascular thrombus would seem more likely in the early stages when there was a soft necrotic focus than later when it had become organised But some work of De Navasquez (1956) is interesting in this connection When pyelonephritis was induced in rabbits by the injection of coagulase positive staphylococci, most of them made a good recovery but were left with scattered scars in the kidney He found that in these rabbits, but not in others without these damaged areas, intravenous injection of gram negative bacteria could now cause serious pyelonephritis It is possible that old scarred areas in the brain may provide a site for the lodgment of bacteria and the development of an abscess, especially if, because of a right-to-left shunt, bacteria reach the brain in larger numbers than usual

Some of the cases where thrombosis was possible or certain will be described shortly The first two might have had an infected embolism or a thrombosis that quickly became infected The others illustrate the frequency of cerebral thrombosis

Case 15—A girl, aged 12, had Fallot's tetralogy with complete situs inversus Six weeks after an uneventful cardiac catheterisation she was admitted to hospital complaining of giddiness, and a disinclination to do things These symptoms had become worse the day before She was drowsy and resented interference, and had a temperature of 103°F, some infection of the gums and mouth, and a few petechial hæmorrhages, but no palpable spleen Next day she was more comatose and could not move her right arm and leg Lumbar puncture showed a cloudy fluid under increased pressure (270 mm of water), with 4750 cells per c mm, and 200 mg protein, and 685 mg chlorides, each per 100 ml Penicillin, 500,000 units 4 hourly, was continued for a month her temperature settled after 3 days, except for occasional spikes and the cell content, protein, and chlorides gradually returned to normal A cerebral abscess was suspected and she was transferred to Hill End Hospital for surgical treatment, but investigations there were inconclusive and it was thought that an infected cerebral embolism might have been the cause of her recent illness She was discharged with some recovery of the right leg but not much in the right hand Subsequently, after a successful operation for her heart, she has by hard work overcome most of the disability in her leg

Case 16—A girl, aged 12, had a patent ductus arteriosus This was closed and her heart became smaller (cardio thoracic ratio 61 to 54%) 28 months later she was admitted to hospital because she had been wakened by a severe headache vomiting and a stiff neck had followed and meningitis was suspected. Lumbar puncture 5 days later yielded a xanthochromic fluid with a protein content of 250 mg per 100 ml, and 100 white cells per c mm, mainly polymorphs 2 weeks later she was transferred to a neurosurgical centre and was found to have papillœdema and a left sided homonymous hemianopia without other localising signs There was some pyrexia and a palpable spleen, but no other evidence of bacterial endocarditis, and blood culture was negative there was no infection of the ears or of the paranasal sinuses An abscess in the right temporal lobe was aspirated and after this and penicillin treatment she improved and lost all her abnormal physical signs

The sudden onset of headache sufficient to waken her from sleep, followed by vomiting and stiffness of the neck, and the xanthochromic lumbar spinal fluid some 5 days later, were thought to suggest a cerebral vascular lesion, an embolic infarct having become infected so that the blood clot had become an abscess by the time of her operation, but no source for an embolism was found Her subsequent progress has been satisfactory

In case 9, no evidence of a vascular occlusion could be found to account for the left sided abscess and right hemiplegia, but 5 years before he had had a left hemiplegia and there was atrophy of the lower half of the middle of the right parietal lobe, involving the motor area and pre motor and post-motor cortex, part of the island of Reil, and the adjoining gyri of the upper temporal lobe this presumably accounted for his old left hemiplegia and must have been due to an old middle cerebral occlusion

A boy, aged 5 years, with a bilocular heart and severe pulmonary stenosis, was thought to have a cerebral abscess, but at necropsy there was a large area of softening in the left external capsule that had probably followed thrombosis some months earlier, and a much smaller area in the right frontal lobe that had been present only for days The older thrombotic area may have been present before his operation or may have followed this, and infection may have been prevented by the vigorous antibiotic treatment (case 9, Campbell and Forgacs 1953)

Two other patients, each with a single ventricle (cases 5 and 6, Campbell et al 1953) can be mentioned in one there was extensive thrombosis of the left vertebral artery extending along the posterior inferior cerebellar artery, and in the second a large area of cortical atrophy in the left temporoparietal region that may have followed thrombosis Our case 2, in addition to multiple abscesses, had some tuberculous arteritis and phlebitis that had led to an early ischæmic necrosis of the lateral aspect of the pons

These cases illustrate the tendency to cerebral thrombosis in patients with cyanotic heart-disease, and some of the abscesses may be due to secondary infection of such thrombi from bacteræmia

Summary and Conclusions

15 examples of cerebral abscess occurring in patients who were seen first for cyanotic congenital heart-disease have been described From these and from the others that have been reported, there is no doubt that a hæmatogenous brain abscess without any obvious primary infection occurs much more frequently in subjects with a right-to left shunt than in others

Reasons have been given for thinking that chance bacteria in the blood stream cannot provide the whole explanation even in the presence of a right-to-left shunt There is no evidence that these abscesses follow minor lung infections

Paradoxical embolism, perhaps the most widely accepted explanation, seems likely, for it would allow infected thrombi from systemic veins to pass readily to the cerebrum It probably accounts for some brain abscesses, but if it were the only cause there should be more cases with emboli elsewhere and more with evidence of the primary thrombus

We think that thrombosis in the cerebral vessels with secondary infection from chance bacteræmia is a frequent cause At first sight this seems to discard the hypothesis that the right-to left shunt is fundamentally important, but it does not, for patients with such a shunt are anoxæmic and polycythæmic and, therefore, prone to cerebral thrombosis, and in addition the right to left shunt makes it easier for bacteria to reach the cerebral circulation without passing through the lungs

We are most grateful to Sir Charles Symonds and to Dr S De Navasquez for helpful criticism of this paper We should like to thank many colleagues for their help with these patients—Sir Charles Symonds, Dr M J McArdle, and Mr Murray Falconer who have taken charge of those patients who have come under my care with a cerebral abscess Also, we should like to thank those who have written to us with details about the subsequent course of these patients Dr Thomas Anderson of Glasgow for case 1, Dr N S Clark and Dr J Watt of Aberdeen for case 6, Mr D Simpson and Dr M Zambellas of Oxford for case 7, Dr R C B Pugh of Great Ormond Street for case 9, the staff of Oldchurch County Hospital for case 10, and the late Mr C A Calvert of Belfast for case 16

My friend Dr Heim de Balsac has kindly informed me that Gilbert Ballet was Professor of Medicine of Paris he published more than two hundred papers, but many of these were of neurological subjects and only two or three on congenital heart disease

URINARY TRACT INFECTION IN A MALE UROLOGICAL WARD

WITH SPECIAL REFERENCE TO THE MODE OF INFECTION

A A C Dutton
M A, B M Oxfd
ASSISTANT LECTURER

Mary Ralston
M B Sydney, D C P
REGISTRAR

DEPARTMENT OF PATHOLOGY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

During routine examination of urine from male urological patients in the genito urinary ward of the hospital, infection was found to be frequent We therefore decided to investigate (1) the incidence and (2) the mode of infection

Two possible modes of infection were suggested —namely, auto-infection (by the patient's intestinal flora) and cross-infection If auto-infection were common, the organisms found in the urine should also be found in the fæces (Since they were mostly antibiotic resistant, they would presumably have appeared in the intestine after the patient's admission to hospital) If cross-infection were to blame, the organisms should be recoverable from sites from which they could be transmitted to patients Both these possibilities were examined

Material and Methods

The series comprised 80 unselected patients—35 with benign prostatic hyperplasia, 7 with carcinoma of the prostate, 10 with other urinary-tract neoplasms, 9 with urinary-tract calculi, and 19 with miscellaneous urological conditions Patients were included in the series if the whole of their stay in the ward fell within the period of investigation and was not less than seven days Only patients passing urine containing both pus cells and bacteria were regarded as infected

Examination of Urine

Urine was collected once or twice a week either from an indwelling catheter or as a " mid stream " specimen Wet preparations and gram stained films of the centrifuged deposit were examined Samples of uncentrifuged urine were cultured aerobically on blood agar and MacConkey agar plates for eighteen hours at 37°C

Identification of Species

Species other than *Staphylococcus pyogenes*, *Streptococcus fæcalis*, *Pseudomonas pyocyanea*, and those of *Enterobacter* genera (*Bergey's Manual* 1948) were isolated so rarely that they are disregarded here Typing was done whenever possible, to help identify strains of probably common origin

Staph pyogenes, *Strep fæcalis*, and *Ps pyocyanea* were identified in the usual way Strains of *Staph pyogenes* were confirmed as such by a slide coagulase test and were phage typed Strains of the other two species were not typed

Enterobacter genera were provisionally identified by the laboratory's routine range of biochemical tests representative strains (excluding *Proteus* species) were investigated more fully by Dr Ørskov, of the Statens Seruminstitut, Copenhagen, using biochemical tests, and were classified as *Escherichia coli*, *Esch freundii* (*Citrobacter*), *Cloaca*, *Klebsiella*, or *Providence* (Kauffmann 1951) Strains of *Esch coli* were identified serologically by their O antigens, and *Klebsiella* by their capsule types (capsule swelling reaction) A few strains not examined by Dr Ørskov are referred to as "coliform bacilli"

The four species of *Proteus* were identified biochemically One organism frequently isolated in this investigation resembled *Pr vulgaris* but did not produce indole after eighteen hours' incubation, it is referred to as *Pr vulgaris* (indole negative) Few of the strains of any proteus species swarmed readily However, in the case of *Pr mirabilis* it was possible to compare certain strains by the Dienes phenomenon Dienes (1946) observed that, when two different swarming strains of *Proteus* converge a narrow line of demarcation remains between the advancing edges of the cultures Kriller (1953) has shown that, with few exceptions, there is no such

TABLE I—INCIDENCE OF URINARY INFECTION IN RELATION TO DIAGNOSIS AND SURGICAL PROCEDURES

Diagnosis	No of cases	Uninfected throughout	Became infected in hospital				Already infected on admission
				Infection followed*			
		No of cases	No of cases	Catheterisation (indwelling)	Instrumentation	Operation	No of cases
Benign prostatic hyperplasia	35	2	22	16	0	2	13 (2)
Carcinoma of prostate	7	4	2	1	1	0	2 (1)
Other urological conditions	38	16	11	2	6	3	11
Neoplasms	10	3	6				1
Calculi	9	3	2				4
Miscellaneous	19	10	3				6
Total	80	22	35	19	7	5	26 (3)

Figures in parentheses = readmissions counted twice

* Data not available for 4 patients with benign prostatic hyperplasia

demarcation between antigenically identical strains, particularly if the flagellar antigens are the same A line of demarcation appears if the antigenic structure is different

Drug sensitivity Tests

The sensitivity of nearly all the strains was tested against streptomycin, chloramphenicol, chlortetracycline (aureomycin), and oxytetracycline (terramycin) by a ditch plate technique Sulphonamide sensitivity was tested on laked horse blood agar containing sulphathiazole (10 mg per 100 ml of agar) *Staph pyogenes* and *Strep fæcalis* were also tested on ditch plates for their sensitivity to penicillin and erythromycin, and *Enterobacter* species and *Ps pyocyanea* for their sensitivity to polymyxin The Oxford staphylococcus was used as control organism for all sensitivity tests except polymyxin, where a sensitive strain of *Esch coli* was used

Incidence of Infection

The clinical diagnosis and the stage at which patients became infected are presented in table I

Of 35 patients with benign prostatic hyperplasia, 2 remained uninfected, 22 became infected in hospital, and 11 were already infected on admission

Of 7 patients with carcinoma of the prostate 4 remained uninfected, 2 became infected, and 1 was already infected on admission

Of 38 patients in the third (miscellaneous) group 16 remained uninfected, 11 became infected, and 11 were already infected on admission

Nearly all the patients who became infected in hospital showed infection within a few days of the insertion of an indwelling catheter or other instrumentation, and before operation

Evidence of Cross-infection

The bacteriological findings provide strong evidence of cross infection In view of the high proportion of patients who became infected after admission, special attention was directed towards organisms acquired in the ward Table II lists all the organisms isolated from patients who became infected after admission, and also the additional organisms acquired in hospital by patients already infected on admission The table shows the number of patients infected by each species, and, where typing was done, the number of patients infected by the most commonly occurring strain The drug sensitivity is also given. Table III deals in a similar way with organisms isolated from the first specimens of urine from patients already infected on admission No strain of typed species was isolated from more than one patient in this group

Evidence of cross infection among patients infected in hospital is seen in the following organisms *Staph pyogenes*, with 11 of 22 patients infected by the same phage-type, *Klebsiella*, with 7 of 9 patients infected by the same strain (i e, being of the same capsule type), *Pr mirabilis*, with the same strain from 8 of 11 patients when tested by the Dienes phenomenon * Further supporting evidence of cross infection is provided by the incidence of infection by *Providence, Pr vulgaris* (indole negative), and *Esch freundii* one strain (identified by its biochemical and sensitivity pattern) of each species infected 17, 14, and 4 patients respectively These organisms are very rarely found in urinary infections elsewhere in the hospital In the present series they were isolated only from the urine of patients infected after admission

In all, 38 of the 58 patients infected in hospital were infected by the predominant strain of one or more of these species

In contrast to these patients, the strains of *Esch coli* infecting the 8 patients on admission were each of a different O antigenic type The strain subsequently isolated from the single patient infected by *Esch coli* after admission was one of these types

The drug sensitivity (table II) was characteristically that of hospital infection Organisms which were naturally sensitive were commonly resistant to penicillin, streptomycin, and sulphathiazole, the drugs most often used in the ward These resistant organisms were isolated from patients before any chemotherapy was given With *Staph pyogenes* 25 of 28 strains were resistant to penicillin,

Ps pyocyanea	2							2	0	0	2	0	0	2	0	0	1	1	0	2	0	1	1

S sensitive　　P partly sensitive but less sensitive than the Oxford *Staphylococcus*　　R resistant

24 of 29 strains were resistant to streptomycin, and 24 of 29 strains were resistant to sulphathiazole A similar picture was seen with *Pr vulgaris*, *Pr mirabilis*, *Klebsiella*, and *Esch freundii* in relation to streptomycin and sulphathiazole, organisms naturally sensitive to both drugs In contrast the strains of *Esch coli* isolated from patients infected on admission were sensitive

Evidence of Auto-infection

It has already been pointed out that, since most of the infecting organisms were antibiotic-resistant, if auto-infection took place it must be by organisms appearing in the intestines after admission to hospital This could happen as a result either of antibiotic therapy or of the ingestion of such organisms The finding of the same strains in many patients indicates that they were cross infected by some route Therefore if auto infection took place in these patients it was subsequent to the ingestion of the infecting organisms and not due to chemotherapy In other patients, where we were unable to establish evidence of cross infection, either of these mechanisms was possible In both groups, however, if auto infection took place, the species infecting the urinary tract should be recoverable from the fæces

TABLE IV—INCIDENCE OF URINARY ORGANISMS IN FÆCES OF 29 PATIENTS INFECTED WITH STREPTOMYCIN-RESISTANT BACTERIA

Organism	Urine	Fæces†				
	No of patients infected*	Before infection			During infection	
		Positive	Negative	Not tested	Positive	Negative
Staph pyogenes	9	0	6	3	0	3
Esch freundii	2	0	1	1	1	0
Klebsiella	3	0	2	1	0	1
Providence	9	0	2	7	0	7
Pr vulgaris indole positive	2	0	2	0	0	0
Pr vulgaris indole negative	6	0	5	1	0	1
Pr mirabilis	6	2	3	1	2	0
Pr morgani	2	0	2	0	0	0
Pr rettgeri	14	1	8	5	0	5
Ps pyocyanea	5	0	3	2	0	2

* 22 patients were infected by more than one organism
† 2–4 specimens per patient the inoculum count for each specimen being 10^6–10^7 organisms

From two to four samples of fæces from 41 unselected patients were examined quantitatively Samples were homogenised in saline solution and several dilutions plated on blood agar and MacConkey's agar Since most of the urinary organisms were streptomycin resistant, the heavier inocula were also plated on the same media to which streptomycin (50 µg per ml of agar) had been added The quantity of fæces used was increased during the investigation to very thick inocula containing 3 mg of fæces The total viable aerobic organisms, excluding streptococci, were counted and the number of them in the heaviest inoculum was estimated Organisms causing urinary infection were counted on the streptomycin-containing plates Organisms were identified as described above

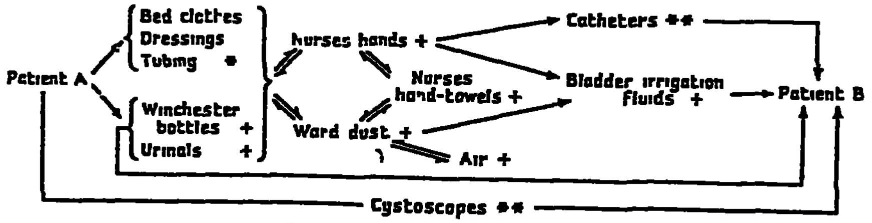
Data from 29 patients with streptomycin-resistant urinary infections are presented in table IV, which shows that, in nearly all instances (representing 23 patients), urinary strains were absent from any fæcal samples taken either before urinary infection developed or on the same day as the first infected specimen of urine was found In 3 cases species causing urinary infection were recovered from the fæces before urinary infection developed, constituting 0 001%, 0 9%, and 2% of the total flora In a further 3 cases the proportion was 1 in 3 × 10^5, 0 15%, and 6% of the flora of the first samples, these being taken on the same day as the first infected urine The remaining 12 patients were not infected with streptomycin resistant organisms—in no case were streptomycin-resistant organisms found in the fæces Thus the fæces of 35 of 41 patients did not yield streptomycin-resistant organisms The possibility of a few cases of auto infection remains

It will be seen from table IV that there were no *Esch coli* infections If auto infection were a common mode of infection, one would expect a high incidence of infection by this intestinal organism

These results provide strong evidence that the bacteria causing urinary infection could seldom have been derived from the patient's intestinal tract Presumably, therefore they were exogenously acquired

Potential Routes of Cross-infection

Possible routes of cross-infection are indicated in the accompanying figure Bacteriological studies were made on the following Winchester bottles used for collecting urine from patients with indwelling catheters, urinals ready for re use, nurses' communal hand-towels, nurses' hands, solutions used for bladder irrigations, catheters, cystoscopes; air, and ward dust Table V shows that the same species as isolated from patients' urine were recovered from all these sites except catheters and cystoscopes



Possible routes of cross-infection

* tubing leading from catheter to Winchester bottles, ** tests made and no urinary organisms isolated, + tests made and urinary strains isolated

* Lactose fermenting "coliform bacilli" not of types isolated from urine were also recovered

† The commonest air type was the same as the commonest urine type

Winchester Bottles

When these were in use, a rubber-tubing extension from the catheter hung free in the bottle, which was not stoppered The bottles were treated routinely before re-use by rinsing out with water followed by the addition of 10 ml of toluene as antiseptic

To each of six Winchester bottles ready for routine use 2 litres of nutrient broth were added, and the bottles were incubated for eighteen hours at 37°C From two of the six bottles *Strep fæcalis* was recovered It was concluded that the treatment of the bottles was inadequate for sterilisation

It was considered that organisms present in a contaminated Winchester bottle, or those gaining access to it from the air, might multiply in the collected urine and reach the bladder by growth up the drainage tubing To test this hypothesis several mock bladder-drainage systems were set up in the laboratory

The bladders were represented by laboratory aspirator bottles, the outlet of each of which was connected to a rubber catheter and tubing which drained into a Winchester bottle One litre of urine was poured into the aspirator, which was then sterilised Several Winchester bottles containing broth were artificially contaminated with various combinations of urinary infecting strains of *Staph pyogenes*, *Strep fæcalis*, *Esch coli*, *Providence*, and 3 *Proteus* species They were incubated till a perceptible but light growth was obtained and were then washed out several times with water, and 10 ml of toluene was added Four feet of rubber tubing, similar to that used in the ward, hung from each aspirator containing urine into an infected Winchester bottle A flow of urine from the aspirator was started and was controlled to flow intermittently for twenty four hours to simulate natural conditions

When Winchester bottles were infected with *Staph pyogenes* and *Strep fæcalis* these organisms were recovered from both the Winchester bottles and the aspirators When Winchester bottles were infected with gram-negative bacilli, none of these species was recovered from either the Winchester or the aspirator bottles We concluded that gram-negative bacilli were destroyed by the routine treatment given to the Winchester bottles, but that gram-positive cocci survive and can ascend to the bladder

Urinals

Broth was pipetted into twelve glass urinals which had been rinsed out in water after use and awaited reissue to patients The urinals were then plugged and incubated for eighteen hours at 37°C

Nurses' Communal Hand-towels

Several towels in use were immersed in broth in large flasks, which were then incubated

Nurses' Hands

Sterile finger-stalls moistened with nutrient broth were worn on the index, middle, and ring fingers of the right hand for thirty minutes they were then removed and the inside was rinsed with broth, which was then cultured When they were worn by nurses on routine ward duties, they yielded organisms of all the species listed in table v except *Esch coli* When they were put on after the routine "wash-up" before irrigating the bladder, *Staph pyogenes* (a urinary infecting type) was recovered as well as an antigenic type of *Esch coli* not previously isolated

Contamination of the nurses' hands during bedmaking was also investigated For this experiment the nurse first "scrubbed up" for five minutes and then dried her hands on a sterile towel Culture of the fingers at this stage proved sterile After "scrubbing up" and drying once more she did the routine bedmaking round At its conclusion a repeat finger-culture yielded one of the urinary strains of *Esch coli* together with other non-urinary type organisms

The results of these tests indicate that the nurses carried on their hands a representative range of organisms that infect the urinary tract, and that these organisms could be recovered even after the hands had been prepared for a bladder irrigation

Bladder-irrigation Fluids

As species of organisms that infect the urinary tract were isolated from the hands of nurses on various occasions, it seemed possible that the fluids used for bladder irrigation might be contaminated from this source Cultures of samples of such fluids from loaded syringes immediately before injection into patients yielded pathogenic species on 18 of 27 occasions (table vi) Cultures from the stock bottles of commonly used fluids (saline solution, 1 1000 mercury oxycyanide, and 1 1000 silver nitrate) were sterile, but samples of distilled water used as diluent, taken from stock bottles and sterile bowls on the trolley in use, yielded *Strep fæcalis* and *Staph pyogenes* on several occasions The organisms recovered from fluid in syringes included additional species acquired during later stages of preparation for the irrigation These may possibly have been derived from the environment, but the nurses' hands seems a more probable source

Catheters

Seven catheters (Tiemann and Foley types used in the ward) were cultured in broth after routine sterilisation by immersion in boiling water for three minutes No urinary species was recovered

Cystoscopes

The sheaths of three cystoscopes were each totally immersed in broth cultures of a representative range of urinary organisms The cystoscopes were then replaced

TABLE VI—URINARY ORGANISMS RECOVERED FROM FLUIDS FROM BLADDER IRRIGATION SYRINGES IMMEDIATELY BEFORE USE

Bladder washout fluid	No of tests	No of tests yielding pathogenic species	No of tests in which each pathogenic species was isolated

* Same phage type as that isolated from operation wounds of 4 patients in ward

† Urinary type

in their metal containers and immersed in boiling water for two and a half minutes After this each cystoscope was immersed in sterile broth and incubated overnight No urinary species was recovered

In view of the negative findings in the cases of catheters and cystoscopes, *syringes* used for bladder irrigation and sterilised by immersion in boiling water were not investigated

Air and Dust

A Bourdillon slit-sampler was operated non-quantitatively in the ward during bedmaking In addition, containers holding erythromycin broth were exposed in the ward to facilitate the recovery of gram-negative organisms

Floor sweepings were collected with sterile brush and pan They were cultured in nutrient broth and also, to facilitate the recovery of gram-negative bacilli, on this occasion in bacitracin broth

The findings are shown in table v

The strains of *Staph pyogenes, Esch coli, Klebsiella,* and *Pr mirabilis* obtained from these various sources were typed and proved identical with the urine strains, except that coliform bacilli and strains of *Staph pyogenes* isolated from bladder irrigation fluids were not of any urinary types Strains of *Staph pyogenes,* however, isolated from fluids diluted ready for two irrigations on one day and two on another day, were of two types isolated from the operation wounds of several patients The identification of *Esch freundii, Providence, Pr vulgaris* (indole-negative) and *Pr rettgeri* as urinary infecting strains was based on biochemical data and drug sensitivity Other organisms were not typed

Discussion

That urinary infection is common in urological wards, particularly among prostatectomy cases, is well recognised, but the mode of infection is less certain Auto-infection has been suggested by Hjort and Sletvold (1945), Kimmelman et al (1951), and Story (1954) Story found that 64 of 119 patients with *Proteus* infection of the urinary tract carried a rectal strain which, on the basis of the Dienes phenomenon, was identical with their urinary strain However, as he pointed out, the urinary infection was already established when the rectal specimen was taken It seems to us that perineal and anal contamination could readily lead to the recovery of *Proteus* from a rectal swab culture, particularly since Story used a technique which would yield organisms present only in very small numbers

Most of the infecting species encountered are intestinal organisms, but in our investigation the infections acquired in this ward seem to have been mainly due to transfer of organisms from one patient to another and not to transfer from the patient's own intestinal tract

Published reports of cross infection of the urinary tract are few Ørskov (1952, 1954) reports findings similar to our own in a study of *Klebsiella* infections of the urinary tract The same strain was often isolated from patients in the same ward, and this strain was recovered from various sites in the ward

Our investigation of the possible sources of cross infection shows that the ward dust and the air are a permanent reservoir of species that infect the urinary tract (This state of affairs has long been realised in connection with other types of cross infection) Also infection may pass from one patient to another via the Winchester bottles used to collect urine from patients with indwelling catheters and possibly via the urinals

In a urological ward some degree of contamination of the nurses' hands seems more or less inevitable, but such contamination is clearly an important cause of cross infection The risk with some procedures (e g, bladder irrigation) is obvious, but incidental procedures, such as reconnecting the drain tube when it has been detached from the catheter might equally transfer organisms to the patient

Procedures in this ward are to be altered in the light of our findings, and the incidence of infection will be estimated again after they have been introduced

Cross-infection of the urinary tract has a special significance now that an increasing proportion of hospital strains of bacteria are resistant to antibiotics

Summary

An investigation of urinary-tract infection in 80 unselected patients in a male urological ward is reported

Of 35 patients with benign prostatic hyperplasia 22 became infected in hospital Of the remaining 45 patients, with various urological conditions, 13 became infected in hospital

Two possible modes of infection were investigated —auto-infection from the patient's intestine and cross-infection

There was little evidence of auto infection Samples of fæces from 41 patients were examined quantitatively for urinary organisms, excluding streptococci, using media containing streptomycin since nearly all the infecting strains were streptomycin-resistant No urinary infecting organisms were isolated from any samples from 23 of 29 patients infected with streptomycin-resistant organisms or from the 12 other patients investigated The possibility remains of occasional cases of auto infection

There was conclusive evidence of cross-infection in a high proportion of the patients Of 58 infected patients 38 were infected by strains of organisms recovered also from other patients The numbers of patients infected by the predominant strain of each species were *Staph pyogenes* (11), *Esch freundii* (4), *Klebsiella* (7), *Providence* (17), and an indole-negative strain of *Pr vulgaris* (14), and strains of *Pr mirabilis* from 8 of 11 patients were the same type

The drug sensitivity was characteristic of that found in hospital infections Resistant strains were isolated from patients who had been infected after admission but before any chemotherapy was given In contrast, strains of *Esch coli* recovered from patients already infected at admission were sensitive and were all of different serological types

A number of potential sources of cross infection investigated yielded one or more urinary infecting strains—Winchester bottles used for collecting urine from patients with indwelling catheters, urinals, nurses' ward hand-towels, nurses' hands, fluids from bladder-irrigation syringes immediately before use, air, and dust Boilable catheters and cystoscopes gave negative results

Mock bladder drainage systems were set up in the laboratory and both *Staph pyogenes* and *Strep fæcalis* (but not gram-negative bacilli) survived the routine chemical disinfection treatment given to Winchester bottles and ascended from these along sterile tubing to the "bladder" against a flow of sterile urine

We are deeply indebted to Dr William Hayes for his continued help and advice and to Lord Stamp and Mr Ralph Shackman for their interest and encouragement We should like to thank the nurses of the urological ward for their willing coöperation Dr F Ørskov, of the Statens Seruminstitut, Copenhagen, kindly examined the strains of *Enterobacter* species, and Dr R E O Williams, of the Staphylococcus Reference Laboratory, Colindale, typed the strains of *Staph pyogenes*

IT has previously been reported by Strisower et al (1954, 1955) that dried thyroid exerts a profound influence on low-density serum lipoprotein and serum cholesterol levels

Strisower et al (1954) reported the effect of 650 mg of dried thyroid substance administered daily for about ten weeks, in each of 11 cases on this dosage of thyroid the levels of cholesterol and of S_f 0–12 and S_f 12–20 lipoprotein in the serum fell considerably throughout the treatment with thyroid , The levels of S_f 20–100 and S_f 100–400 lipoprotein did not fall so uniformly during thyroid treatment That study was designed to test the response to a very high dosage of thyroid The discovery that all patients respond to a high dosage of thyroid by a fall in serum lipoprotein and serum-cholesterol levels led to the study of the response to lower doses of thyroid

A long term study was therefore initiated, starting with a dosage of 195 mg daily Strisower et al (1955) have reported the results of thirty weeks' administration of this dosage of thyroid A considerable fall in the levels of S_f 0–12, and S_f 12–20 lipoprotein and cholesterol in the serum was observed initially on this dosage in 50 patients , but, in spite of continued administration of thyroid, the great majority of patients showed an apparent "escape" phenomenon the lipoprotein and cholesterol levels, maximally depressed at three weeks after the start of thyroid treatment, gradually returned towards the pre treatment values until, at thirty weeks, they were almost up to the pre treatment values

The hypothesis was advanced that this "escape" phenomenon was, in all likelihood, due to a gradual cessation of production of endogenous thyroid hormone, with the result that the amount of thyroid hormone available daily to the patient after thirty weeks' administration of dried thyroid 195 mg daily was not appreciably above the amount of hormone available before such treatment It was expected that, if the dosage of dried thyroid were increased sufficiently, a point would be reached where the sum of endogenous and exogenous thyroid hormone would exceed that produced daily before such treatment, and that the lipoprotein and cholesterol levels in the serum would remain low

This concept has been tested now by extending the original treatment period of thirty weeks' thyroid 195 mg daily to include two additional periods thirty-nine weeks' thyroid 260 mg daily, and thirty six weeks' thyroid 325 mg daily These studies are reported here

Materials and Methods

Sixty schizophrenic patients at Stockton State Hospital were chosen for the experiment So far as could be determined, these patients were physically and metabolically normal There were thirty females aged 27–56 (mean 39 6) and thirty males aged 25–57 (mean 40 3) The only selection used in constituting the group was that each patient's mental status made both leave and discharge from the hospital during the experiment very unlikely *

Two important requirements of an experiment to test the efficacy of a drug such as dried thyroid in lowering the serum-lipoprotein levels are met by using chronic mental patients (1) a stable diet, such as that of an institution, because it is well known that alterations in the diet exert profound effects on the levels and distribution of lipoproteins (Glazier et al 1954, Gofman et al 1954, Nichols et al 1956) , and (2) assurance that the drug is taken consistently by each patient

Two samples of blood were taken for estimating the lipoprotein and cholesterol levels before the administration of dried thyroid At the same time body weight blood-pressure, and pulse rate were recorded Treatment with dried thyroid was begun in twenty patients (ten male and ten female) in each of three succeeding weeks Samples of blood were taken on the same staggered schedule at three-week intervals during the first two periods of the experiment and later at six-week intervals, body weight, blood pressure, and pulse rate being recorded at the time that each sample of blood was taken The lipoprotein and cholesterol levels in the serum were measured by techniques previously described by de Lalla and Gofman (1954) and Colman and McPhee (1956) The treatment with dried thyroid was deliberately started at different times so that blood sampling would also be done in different weeks to minimise the effect of any small technical variations in the estimation of serum lipoproteins and serum cholesterol

The dosage of dried thyroid was maintained at 195 mg daily for an initial period of thirty weeks, followed by 260 mg daily for thirty-nine weeks and 325 mg daily for thirty-six weeks

The patients were followed up for twenty-seven weeks after the treatment had been stopped, samples of blood being taken and body-weight, blood-pressure, and pulse-rate being recorded at three, six, twelve, and twenty seven weeks after the end of treatment

Of the original sixty patients thirty nine completed the course of thyroid The twenty-one who did not complete the course are accounted for as follows

(1) Six patients were transferred to a different ward for active psychiatry There was no indication that the thyroid had made the transfer necessary

(2) One patient was transferred to a surgical ward for hæmorrhoidectomy

(3) Two patients refused to allow further samples of blood to be taken

(4) Six patients left the hospital

(5) Four patients lost so much weight that, in view of possible thyrotoxic effects, they were excluded from the experiment

(6) Two patients showed increased agitation, which, although probably not due to thyroid treatment, led to their exclusion from the experiment

Results

The mean changes in the levels of the four classes of low density lipoproteins (S_f 0–12, S_f 12–20, S_f 20–100, S_f 100–400) and of cholesterol in the serum of the thirty nine patients who completed the course of treatment are shown in fig 1 From the data plotted in fig 1 and significance tests the following results can be deduced

---

* This experiment was begun in June, 1953, before the common use of such therapeutic agents as reserpine and chlorpromazine At no time in the course of this entire study were such agents administered to any of the patients in this group

(1) *Serum cholesterol*

After three weeks on thyroid 195 mg daily there was a significant ($p<0.01$) fall in the mean level of serum-cholesterol from an initial value of 216 mg per 100 ml to 157 mg per 100 ml Thereafter the mean serum-cholesterol level rose progressively toward the pre-treatment value From twenty-four to thirty weeks after the start of treatment with thyroid 195 mg daily the serum cholesterol level was 210 mg per 100 ml, which does not differ significantly from the initial value when the dosage was increased to 260 mg daily, a significant progressive fall of the serum cholesterol level was observed (mean 184–200 mg per 100 ml throughout most of the treatment with 260 mg daily) Towards the end of the thirty-nine weeks on 260 mg daily and in the first fourteen weeks on 325 mg daily the serum cholesterol level tended to rise

At this stage of the experiment the question arose whether there was real evidence for some "escape" from the effect of the thyroid, or whether the patients were receiving less than the full dosage of 325 mg daily The ward attendants were then re-impressed with the need for very careful attention to administration of the full dosage of the thyroid each day to every patient and were constantly reminded of this throughout the remainder of the experiment After these discussions with the attendants the serum-cholesterol level fell progressively and remained low (mean 195 mg per 100 ml) throughout the remaining twenty-two weeks on 325 mg daily Thus, during treatment with 325 mg daily, when there was reasonable assurance that the patients received the full dose, there was no evidence of an "escape" phenomenon from the effect of thyroid on the serum-cholesterol level

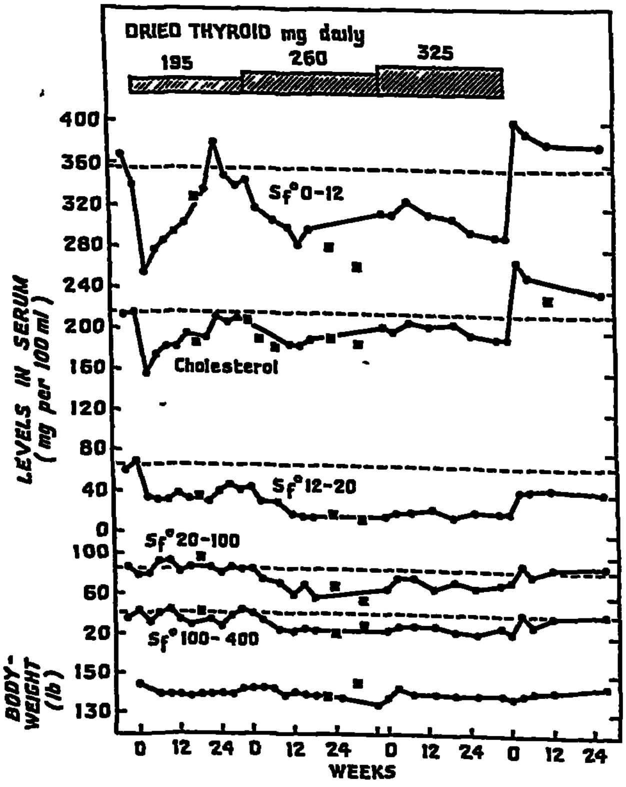

Fig 1—Levels of cholesterol and S_f 0–12 S_f 12–20 S_f 20–100 and S_f 100–400 lipoproteins in serum and body-weights during treatment with dried thyroid 195 mg 260 mg and 325 mg daily and during follow up Interrupted lines means of two pre-treatment readings circular plotting-points means of 30 or more samples square plotting points means of less than 30 samples

Three weeks after the administration of thyroid 325 mg daily had been stopped the serum-cholesterol rose quickly to 269 mg per 100 ml Thereafter it fell gradually to 235 mg per 100 ml and stayed there for the last fifteen weeks of the follow-up

(2) *S_f 0–12 Lipoproteins*

The behaviour of the level of the S_f 0–12 lipoproteins in the serum was roughly the same as that of the serum-cholesterol level On thyroid 195 mg daily the level of the S_f 0–12 lipoproteins fell sharply for three weeks, from its initial value of 354 mg per 100 ml to 256 mg per 100 ml, and then gradually returned to its pre-treatment value at the end of the thirtieth week on 195 mg daily Under treatment with 260 mg daily the mean level of S_f 0–12 lipoproteins fell progressively to about 306 mg per 100 ml The rising trend in the last part of the treatment with 260 mg daily and the first part of the treatment with 325 mg daily corresponded to that observed for the serum-cholesterol level

As with the serum cholesterol level, after the attendants had been warned to make sure that the full doses were given, the levels of S_f 0–12 lipoproteins fell, and remained low at a mean value of 294 mg per 100 ml throughout the rest of the treatment with 325 mg daily No evidence of an "escape" phenomenon was noted

Three weeks after thyroid medication had been stopped, the level of the S_f 0–12 lipoproteins rose quickly to 403 mg per 100 ml and then gradually dropped and stayed at 378 mg per 100 ml twenty seven weeks after the end of treatment

(3) *S_f 12–20 Lipoproteins*

The level of S_f 12–20 lipoproteins fell from 76 mg per 100 ml to 44 mg per 100 ml on the administration of thyroid 195 mg daily In contrast to the levels of S_f 0–12 lipoproteins and cholesterol, the level of S_f 12–20 lipoproteins did not tend to rise under treatment with 195 mg daily, except for a slight increase in the last nine weeks However, even with this increase the levels remained significantly below the pre treatment value When the daily dosage of thyroid was increased to 260 mg the levels of S_f 12–20 lipoproteins dropped further to about 25–30 mg per 100 ml and stayed there for the rest of the treatment with 260 mg daily and throughout the treatment with 325 mg daily

When the thyroid treatment was stopped, there was a significant rise to 52 mg per 100 ml but no rebound above the initial levels During the remainder of the twenty seven weeks' follow-up the level of the S_f 12–20 lipoproteins remained unchanged at 52 mg per 100 ml

(4) *S_f 20–100 and S_f 100–400 Lipoproteins*

In contrast with the findings for cholesterol and the S_f 0–12 and S_f 12–20 lipoproteins, neither the S_f 20–100 nor the S_f 100–400 lipoproteins showed any significant change in mean level during treatment with thyroid 195 mg daily When the dosage was increased to 260 mg daily, the mean levels of both S_f 20–100 and S_f 100–400 lipoproteins gradually fell and remained low during the rest of the treatment with 260 mg and throughout the treatment with 325 mg The level of the S_f 20–100 lipoproteins dropped from an initial mean value of 83 mg per 100 ml to a mean value of 60–70 mg per 100 ml during treatment with 260 mg and with 325 mg The level of the S_f 100–400 lipoproteins was 39 mg per 100 ml initially The mean level of the S_f 100–400 lipoproteins dropped to about 25 mg per 100 ml during treatment with 260 mg and with 325 mg

When the thyroid treatment was stopped, the levels of both the S_f 20–100 and the S_f 100–400 lipoproteins rose within three weeks to the pre-treatment values and stayed there throughout the twenty seven weeks follow up

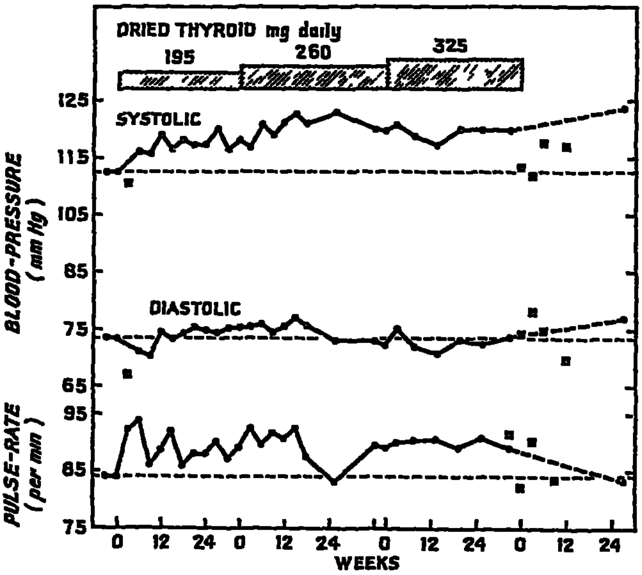

Fig 2—Pulse rate and systolic and diastolic blood pressures during treatment with dried thyroid 195 mg, 260 mg, and 325 mg daily and during follow up Interrupted lines, means of two pre-treatment readings, circular plotting points, means of 30 or more samples, square plotting points means of less than 30 samples

(5) *Body weight*

During the first six weeks' treatment with 195 mg daily the mean body-weight decreased from 145 lb to 140 lb Thereafter, throughout all three periods of treatment (195 mg, 260 mg, and 325 mg daily) the mean weight remained at 140 lb except for oscillations of ±3 lb Fig 1 certainly does not suggest that continued negative caloric balance (and hence continued weight loss) is necessary to produce and maintain falls in the levels of lipoproteins and cholesterol in the serum After the thyroid treatment had been stopped, the body-weight gradually returned to its pre treatment value of 145 lb during the twenty seven weeks' follow-up

(6) *Blood pressure and Pulse rate*

The mean changes in pulse-rate and systolic and diastolic blood-pressure under the different dosages are shown in fig 2

The pulse rate increased from an initial mean value of 84 to an average of about 90 during the entire period on dried thyroid at the three dosages of 195 mg, 260 mg, and 325 mg daily When the thyroid treatment had been stopped, the pulse rate returned to its pre-treatment value

The systolic blood pressure rose gradually from a mean pre treatment level of 112 mm Hg to an average of about 120 mm Hg during treatment with 260 mg and 325 mg daily It remained at 120 mm Hg during the follow-up

The diastolic blood-pressure kept its mean value of 74 mm Hg during the entire period on thyroid and during the follow up The greatest changes observed were ±4 mm Hg

Discussion

The long-term study of the administration of dried thyroid in successive dosages of 195 mg, 260 mg, and 325 mg daily shows that it is possible to produce and maintain depression of the levels of cholesterol and S_f° 0-12, S_f 12-20, S_f 20-100, and S_f 100-400 lipoproteins in the serum The "escape" phenomenon, expressed as a rise in lipoprotein and cholesterol levels, in spite of the continued administration of thyroid 195 mg daily, was previously attributed by us to diminished production of endogenous thyroid hormone As a corollary we predicted that the "escape" phenomenon would be prevented by increasing the dosage of dried thyroid The periods of administration of 260 mg and 325 mg of thyroid showed no "escape" phenomenon Hence the results in these periods support the concept that diminished production of endogenous thyroid hormone was indeed responsible for the "escape" phenomenon observed on a dosage of 195 mg The rebound in levels to values above the initial values on the cessation of thyroid treatment provides further evidence of diminished production of endogenous thyroid hormone Immediately after the thyroid treatment has been stopped—i e, the exogenous supply of thyroid has been withdrawn—if the endogenous production of thyroid has diminished, the immediately available supply of thyroid hormone is less than it was before treatment Therefore the levels should rise above the pre-treatment values As the endogenous supply of thyroid hormone increases, the lipoprotein levels should gradually fall towards the pre-treatment values This was precisely what happened in the later part of the follow-up

In three of the thirty-nine cases the levels of S_f 0-12 lipoproteins in the follow up period still remained more than 25% above the pre-treatment value, even twenty seven weeks after the end of treatment with thyroid In the absence of other reasons for such a rise the possibility must be considered that reversal of inhibition of the thyroid gland is extremely slow or will not take place at all Such slowly reversible or irreversible inhibition of the thyroid gland does not appear to be of any serious consequence, because substitution therapy is readily available in the form of dried thyroid

As one aspect of the effort to understand metabolic factors that might influence the response to dried thyroid, the fall of the serum-lipoprotein level in relation to its pre treatment value was assessed in the patients studied For this purpose the patients were ranked according to the initial levels of the several classes of lipoproteins in their serum and then according to the falls in level of those lipoproteins by the end of the thirty six weeks' treatment with thyroid 325 mg daily From table I it is clear that, whatever lipoprotein is used to rank the patients, the higher the initial level of lipoproteins the greater is its subsequent fall The net effect of therapy with thyroid is to decrease the variability, or range of values, of each class of lipoproteins within the group under study One possible interpretation of this observation is that, in patients with high lipoprotein levels, there is a relative deficiency of that thyroid function which controls lipoproteins

It is possible that the control of metabolism and the control of lipoproteins are two separate functions of the

TABLE I—CHANGE IN LEVELS OF LIPOPROTEINS IN SERUM UNDER TREATMENT WITH DRIED THYROID

Lipoproteins	Initial level (mg per 100 ml)		No of cases	Level at end of treatment (mg per 100 ml)	Change in level (mg per 100 ml)

TABLE II—EFFECT OF DRIED THYROID ON MEAN ATHEROGENIC-INDEX VALUES (UNITS)

Initial	After 30 weeks' thyroid 195 mg	After 39 weeks' thyroid 260 mg	After 36 weeks thyroid 325 mg
70 0	65 7	51 0	52 0

thyroid gland. Goolden (1956) reports that tetraiodothyroacetic acid given to a euthyroid person lowered the plasma cholesterol level without decreasing the body-weight, and Trotter (1956) reports that tri-iodothyroacetic acid lowered the blood-cholesterol level in three euthyroid patients without significantly altering the basal metabolic rate THE LANCET (1956) commented that these newer compounds showed promise of being able to lower the blood-cholesterol level without causing unwanted side effects

Our own observations indicate that considerable caution should be used in setting apart these new thyroid-active substances as being different in their action from dried thyroid, because we find that dried thyroid produces a well-marked effect on the serum lipids in many patients without significantly altering the body-weight Thus, in the present series, eighteen patients lost only 5 lb or less of body-weight in a hundred and two weeks of study, and eight of these actually gained weight In all of them the lipoprotein level was significantly lowered as a result of the administration of dried thyroid In these eighteen patients the mean change in body-weight was + 3 1 lb, and the mean fall in level of S_f 0–400 lipoproteins 41 mg per 100 ml

TABLE III—CHANGES IN MEAN ATHEROGENIC-INDEX VALUES (UNITS) AFTER TREATMENT WITH DRIED THYROID

Initial	After 30 weeks thyroid 195 mg	After 39 weeks' thyroid 260 mg	After 36 weeks' thyroid 325 mg
In 10 patients with highest S_f 0–400 lipoprotein level			
94 1	84 6	62 0	64 0
In 10 patients with lowest S_f 0–400 lipoprotein level			
43 0	46 5	39 9	37 1

Furthermore, fig 1 shows that, from the last part of treatment with 195 mg daily and throughout treatment with 260 mg and with 325 mg daily, there was practically no alteration in weight in any of the patients, although the serum-lipoprotein and serum-cholesterol levels fell during this period In addition, in a separate study of patients with the S_f 0–12 hyperlipoproteinæmia characteristic of xanthoma tendinosum, it was commonly observed that the lipoprotein level fell considerably without loss of body-weight and often with a gain in weight (Gofman et al 1957) We therefore consider that unwanted side effects—e g, weight loss—need not arise in treatment with dried thyroid Therefore if any of the recently studied active compounds produced by the thyroid gland act separately on the lipids and on metabolism to a greater extent than does dried thyroid the demonstration of this fact requires a carefully controlled comparison of the various substances

One field where the effect of dried thyroid on lipoprotein and cholesterol levels is of especial interest is arteriosclerosis especially coronary arteriosclerosis and its sequel, coronary heart-disease Gofman et al (1953) have shown that there is a positive association of the serum levels of the S_f 0–12, S_f 12–20 S_f 20–100 and S_f 100–400 lipoproteins with clinical coronary heart-disease A composite measure called the atherogenic index (A I) value† represents the best combination of the lipoprotein levels in distinguishing patients with overt coronary disease from clinically healthy persons Since raised A I values are associated with increased risk of clinical coronary heart-disease, one reasonable approach to prophylaxis of coronary heart-disease is by trying to reduce raised A I values The effect of dried thyroid in lowering lipoprotein levels and keeping them low suggests its possible application for this purpose The data of fig 1 can be calculated on the basis of A I response to dried thyroid These results are presented in table II

The decrease in A I value during treatment with thyroid 260 mg and with 325 mg is considerable Table I shows that, as already stated, the higher the initial lipoprotein level the greater is the fall in response to thyroid The A I response in the ten patients with the highest initial level of S_f 0–400 lipoproteins is compared with that in the ten patients with the lowest initial level of S_f 0–400 lipoproteins in table III

It is clear that the patients with the highest initial levels showed a considerable decrease of A I value in response to thyroid administration, this decrease should indicate a smaller risk of clinical coronary heart-disease The patients with the lowest initial levels showed a much smaller decrease of A I value, both actual and proportional, their risk of developing clinical coronary heart-disease is already small and is only slightly decreased further by treatment with thyroid From the point of view of possible prophylaxis of coronary heart-disease the much greater effect of thyroid on raised A I values than on low ones is especially useful because it is precisely the patients with high A I values who most need prophylactic lowering of their A I values

Summary

Dried thyroid 260 mg daily and 325 mg daily produces a sustained fall in the levels of S_f 0–12 S_f 12–20, S_f 20–100, and S_f 100–400 lipoproteins and of cholesterol in the serum

The higher the initial level of lipoproteins the greater is the fall in that level under such treatment

"Escape" phenomena, previously observed on thyroid 195 mg daily, were not observed with higher dosages

The large falls in atherogenic index values for patients with high initial atherogenic index values suggest that dried thyroid is worthy of consideration as a prophylactic agent against coronary heart disease

We gratefully acknowledge the assistance of Minnie Adams, Ellen Davis, John Sanders, and the other ward personnel of Stockton State Hospital for administering the dried thyroid, for measuring blood pressures, pulse rates, and body weights, and for drawing the samples of blood We also thank the technical workers at Donner Laboratory for ultracentrifugal analyses, and Alice McPhee, of the Donner Laboratory, for all the serum cholesterol analyses The dried thyroid was supplied by the Armour Laboratories, Kankakee, Illinois This work was partly supported by the United States Atomic Energy Commission, the Albert and Mary Lasker Foundation Inc, and Wyeth Laboratories, Inc, Philadelphia, Pennsylvania

THE INFLUENCE OF TRIIODOTHYROACETIC ACID ON THE CIRCULATING LIPIDS AND LIPOPROTEINS IN EUTHYROID MEN WITH CORONARY DISEASE

M F Oliver
M B Edin , M R C P E
RESEARCH FELLOW, DEPARTMENT OF CARDIOLOGY, ROYAL INFIRMARY, EDINBURGH

G S Boyd
Ph D Edin
LECTURER, DEPARTMENT OF BIOCHEMISTRY, UNIVERSITY OF EDINBURGH

It has now been established beyond reasonable doubt that the circulating cholesterol, the cholesterol/phospholipid ratio, and the proportion of cholesterol which is attached to β lipoprotein are all raised in coronary disease (Morrison et al 1948, Gertler et al 1950, Barr et al 1951, Steiner et al 1952, Nikkila 1953, Oliver and Boyd 1953, Rosenberg et al 1954 Oliver and Boyd 1955) But it has not yet been established in man that correction of the abnormal pattern of circulating lipids and lipoproteins will retard the atherosclerotic process or decrease the tendency to thrombosis Hence any compound which lowers the levels of cholesterol and β lipoprotein cholesterol in the plasma requires consideration

It has been known for many years that thyroid extract lowers the plasma cholesterol and plasma phospholipid levels in hypothyroid and euthyroid subjects and at the same time increases their metabolic requirements (Lévy and Lévy 1931, Turner and Steiner 1939, Gildea et al 1939) More recently it has been shown that thyroxine reduces the β lipoprotein fraction (Malmros and Swahn 1953) Triiodothyroacetic acid (triac), an acetic acid analogue of triiodothyronine first synthesised by Pitt Rivers (1953), also lowers the plasma cholesterol, but in small doses it may not produce a concomitant rise in the basal metabolic rate (B M R) (Lerman and Pitt-Rivers 1955) A similar lowering of the plasma cholesterol without any rise in the B M R has been observed in euthyroid subjects after larger doses of triac (Trotter 1956) and after small doses of triiodothyronine (Oliver and Boyd 1956, Boyd and Oliver 1957)

In general, thyroid derivatives are not suitable for administration to patients with coronary disease, because they may increase metabolic requirements enough to provoke angina and to reduce exercise tolerance, but a derivative which decreases the plasma cholesterol without apparently increasing metabolic requirements has obvious potentialities

Methods

The subjects were twelve hypercholesterolæmic men between the ages of 33 and 49 (mean 42) who had experienced classical myocardial infarction, confirmed electrocardiographically, more than 9 months before the clinical trial of triiodothyroacetic acid All the men had returned to their usual full time occupations, and none of them were off work during the trial or in the 3 months preceding it

The plasma cholesterol was estimated by the Sperry Schoenheimer procedure modified by Sperry and Webb (1950) , the plasma phospholipids were estimated by the method of Allen (1940) , and the distribution of cholesterol between the α and β lipoproteins was estimated by filter paper zone electrophoresis with subsequent elution of cholesterol (Boyd 1954) The B M R was determined on a standard Benedict Roth apparatus by the linear formula of Aub and DuBois (1917) All the men were admitted to hospital for two nights for this purpose, the B M R being determined on two consecutive mornings Electrocardiography was done before the administration of triac, with every change in its dosage and after the end of the course From the start of the course the men attended weekly between 9 A M and 10 A M for withdrawal of blood and recording their weight

Results

Small Dosage

To six men triac was administered orally in divided and increasing doses from 0 5 mg to 4 0 mg daily for 95 days (fig 1). There was no significant change in the levels of the circulating lipids and lipoproteins until 3 0 mg was given daily

At the end of the course, when 4 0 mg had been given daily for 10 days, the mean plasma cholesterol had fallen by 21%, but the mean cholesterol/phospholipid ratio was not significantly altered The proportion of cholesterol attached to β-lipoprotein had fallen by 26% and the proportion attached to α-lipoprotein had risen by 46% There was no loss of weight, and the mean B M R of the six men was not significantly altered the mean readings before the course were +1% and -5% and at the end of the course +1% and –3% There was no significant change in the electrocardiograms during or after the course

In two of the six men the B M R had risen by the end of the course In one of them the B M R rose by 20% and this rise was associated with a fall of 15% in the plasma cholesterol and of 19% in the β lipoprotein cholesterol In the other man the B M R rose by 13% and this rise was associated with a fall of 29% in the plasma cholesterol and of 29% in the β lipoprotein cholesterol This man complained of decreased exercise tolerance and of about three attacks of effort angina daily , previously he had only had angina once or twice weekly on strenuous exertion This increase in the incidence of angina necessitated recourse to glyceryl trinitrate, which he had not required for 3 years

In another man, who previously had excellent exercise tolerance and no angina, the B M R fell during the course

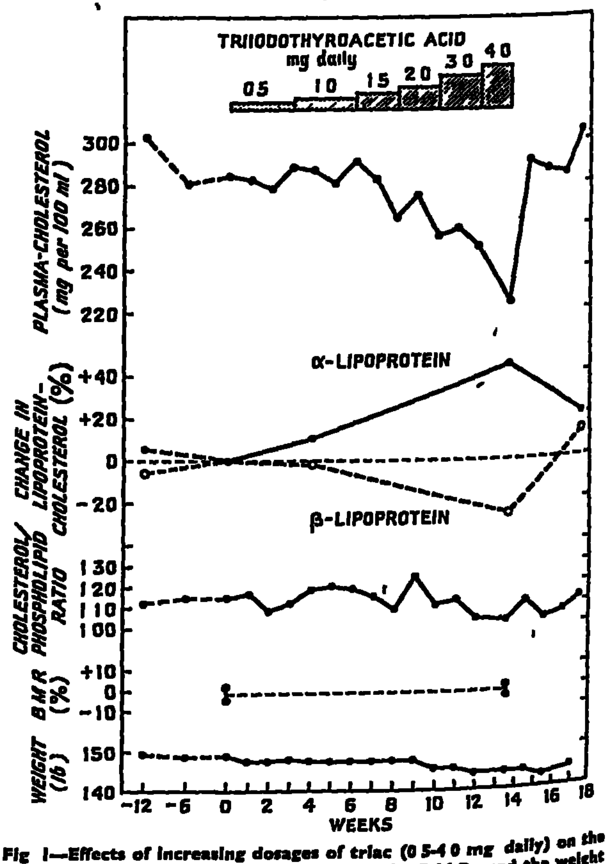

Fig 1—Effects of increasing dosages of triac (0 5-4 0 mg daily) on the plasma levels of lipids and lipoproteins, the B M R , and the weight of six euthyroid men with coronary disease

of triac, but he developed classical angina of effort twice or three times each day, his plasma cholesterol had fallen by 13% and his β-lipoprotein cholesterol by 15%.

When triac was withdrawn, both of these men experienced rapid regression of their symptoms, and they now have little angina or impairment of exercise-tolerance.

Large Dosage

To six men triac was administered orally in divided and increasing doses from 3·0 mg. to 5·0 mg. daily for 3 months (fig. 2).

After 3·0 mg. had been administered daily for 1 month, the mean plasma cholesterol had fallen by 4% and the mean cholesterol/phospholipid ratio by 12%. After the administration of 4·0 mg. daily for a week the plasma-cholesterol had fallen by a further 10% (making a total fall of 14%) and the cholesterol/phospholipid by a further 8% (making a total fall of 20%). After the administration of 4·0 mg. daily for 2 weeks the β-lipoprotein cholesterol had fallen by 12% and the α-lipoprotein cholesterol had risen by 15%. During the subsequent 2 weeks, when the men received 4·0 mg. daily, the plasma cholesterol and the cholesterol/phospholipid ratio rose to control values or higher.

When 5·0 mg. was administered daily for a month, there was a further slight fall in the plasma cholesterol, but this was much less impressive than the original fall at the beginning of the course of triac with the 3·0 mg. dosage. At the end of the administration of 5·0 mg. of triac daily for a month, the proportions of cholesterol attached to α- and β-lipoproteins had returned to control values. When triac was withdrawn, there were rebound rises in the plasma-cholesterol and in the cholesterol/phospholipid ratio.

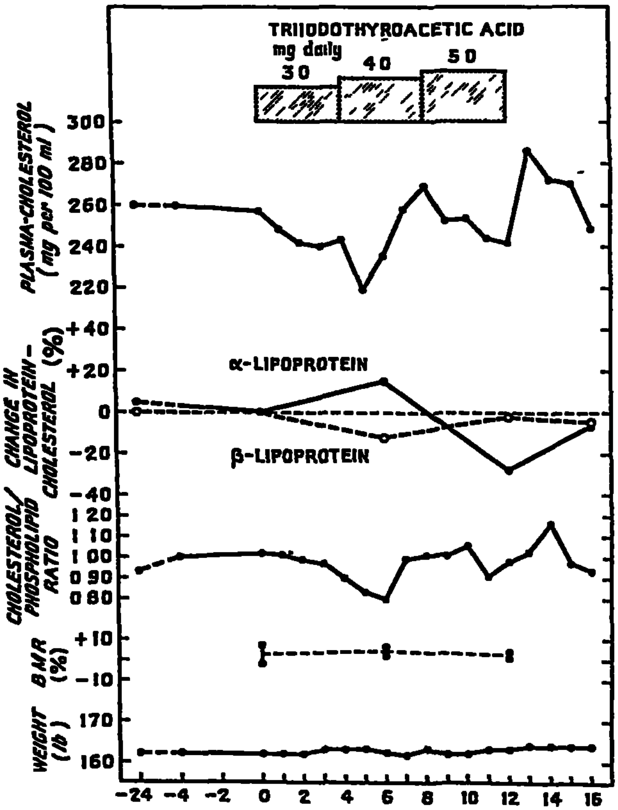

Fig. 2—Effects of increasing doses of triac (3·0-5·0 mg. daily) on the plasma levels of lipids and lipoproteins, the B.M.R., and the weight of six euthyroid men with coronary disease.

There was no loss of weight, and the B.M.R. of these six men was not significantly altered; the mean readings before the course were +7% and −2%, after 6 weeks on triac they were +7% and +2%, and at the end of the course they were +4% and +2%. There was no significant change in the electrocardiograms during or after the course. In one of the six men exercise-tolerance was less, as shown by more angina and breathlessness on exertion.

Discussion

In euthyroid men with coronary disease triiodothyroacetic acid (triac) lowered the plasma cholesterol, the cholesterol/phospholipid ratio, and the proportion of cholesterol attached to β-lipoprotein without raising the basal metabolic rate. The dosage of triac that will produce this dissociation varies from patient to patient, but the optimum is usually 3–4 mg. daily—i.e., six or eight times what is required by hypothyroid patients (Boyd and Oliver 1957).

In three out of twelve men the normally good exercise-tolerance was reduced, and angina developed or was greatly aggravated. In one of these three triac raised the B.M.R., and the reduction of exercise-tolerance is therefore not surprising. In the other two the B.M.R. did not change, yet their exercise-tolerance certainly diminished as was evident from our previous observation of the patients for several years.

It has been shown that the administration of triac to euthyroid and to hypothyroid rats increases the oxygen uptake of heart tissue to a greater extent than that of liver, skeletal muscle, and kidney (Barker and Lewis 1956, Boyd and Oliver 1957). It has been suggested that triac may increase the oxygen requirements of the myocardium without causing any observable increase in the B.M.R. (Boyd and Oliver 1957). It is possible therefore, that the dissociation of its action on the circulating lipids and lipoproteins from any effect on the B.M.R. is more apparent than real; it may depend partly on inadequacy of the B.M.R. to reflect a selective increase in the oxygen requirements of a comparatively small tissue.

Fig. 2 shows that depression of the plasma cholesterol could not be maintained over long periods even when the dosage of triac was increased. In this graded study a comparatively large dosage (such as 5 mg. daily) was no more effective than a smaller one. Moreover such large dosage may be undesirable in some patients because it may induce angina more readily.

Summary and Conclusions

In euthyroid hypercholesterolæmic men with coronary disease triiodothyroacetic acid (triac) lowered the plasma cholesterol, and cholesterol/phospholipid ratio, and the β-lipoprotein cholesterol without raising the basal metabolic rate.

After a course of triac two out of twelve men developed angina of effort, and their exercise tolerance was decreased even though their basal metabolic rates were not raised.

The fall in the plasma cholesterol level could not be maintained for long even by increasing the dosage of triac.

It is concluded that triac may not prove suitable for the long term control of hypercholesterolæmia in patients with clinical coronary disease.

We wish to thank Dr Rae Gilchrist and Prof. G. F. Marrian, F.R.S., for their advice and encouragement, Dr H. M. Walker, of Glaxo Laboratories, for the triiodothyroacetic acid, and Mr Fraser Syme and Mr William Cooper for technical assistance. This research was supported by the Scottish Hospital Endowments Research Trust as part of their programme for the study of coronary disease.

ROVSING'S OPERATION FOR POLYCYSTIC KIDNEY

J G YATES BELL
M B Lond , F R C S
UROLOGICAL SURGEON, KING'S COLLEGE HOSPITAL, LONDON

SINCE Rovsing described his operation in 1911, little has been written about the results obtained Most of the series have been published in the United States, but neither there nor in Britain is the value of the operation widely recognised Apparently most surgeons try it once or twice and then abandon it because the mortality-rate is high This is easy to explain Uræmia is not relieved, and indeed may be fatally aggravated by, Rovsing's operation Hence the surgeons who try it as a last resort in patients deteriorating in spite of medical treatment, are likely to be disappointed On the other hand, those who use it in earlier cases are often more favourably impressed

Catrill and Fish (1941) operated on 23 of their 58 cases with 2 deaths They found that the results were poor when the kidneys were failing

Rathbun (1942) claims that hæmaturia is particularly likely to benefit from Rovsing's operation, and quotes an interesting misadventure leading to nephrectomy

Newman (1950) reviews the literature and observes that all authors claim good results from surgery in polycystic disease, he reports 24 cases treated by operation and maintains that considerable benefit may be expected for pain and bleeding, but not for renal function

Goldstein (1951) treated 18 patients conservatively and 18 by his own operation He claims to have doubled their expectation of life and to have improved their general health by reducing the severity of symptoms

I have been tapping polycystic kidneys for twenty-five years, and have operated on nearly half the patients I have seen I should now recommend surgery for a much higher proportion

Methods

Preoperative Care —Anæmia and disturbances of blood-chemistry should be corrected as far as possible Infection should be treated by the appropriate drug, but streptomycin should never be given to a patient with polycystic kidneys, 3 cases of vestibular destruction have been seen from quite short courses

The Operation —It is strongly recommended that only one kidney be tapped at a time The second can be tapped after fourteen days in fairly fit patients, but in advanced cases some months should be allowed

The patient is placed face-down with a pillow under the chest Edebohl's incision is used The advantage of this is that, when a further tapping is required, the usual curved lumbar approach can be used for the front of the kidney and no scar tissue will be present to make difficulties

The peritoneum, which extends very far posteriorly with the colon over these large kidneys, should be carefully freed towards the front The posterior and postero lateral cysts are punctured, or rather slit, with a small knife (diathermy is not favoured), and, as the kidney shrinks, more and more cysts come into view To avoid shock, the operation should not be prolonged

The ilio inguinal nerve should be protected otherwise there may be postoperative pain The wound is drained for about six days and rarely breaks down

Results

I have operated on 18 patients with polycystic kidneys

There were two postoperative deaths One patient (case 5) died suddenly a week after operation, with a blood-urea of 230 mg per 100 ml In the other (case 14) a biopsy specimen of the polycystic liver was taken at a physician's request To control the bleeding took a long time, she became shocked and soon died

Both were very advanced cases, but in the light of present knowledge they should not have died In case 5 the operation should have been delayed and the man's condition further improved, in case 14 the liver biopsy should have been avoided

This series does not include patients operated on during the war whose notes are lost and who have not been followed up As there was no death after operation in those cases, the mortality-rate in my experience is less than 2 in 18 In most published series it appears to be just under 10% for advanced cases

Of the 16 surviving patients, symptoms were relieved or improved in 15, the other (case 7) had no symptoms but satisfactorily withstood a prostatectomy a month after operation

6 patients were relieved of pain and 5 of bleeding, in 3 renal function improved temporarily 2 with infection were improved

Hypertension is a symptom for which improvement is not usually claimed, yet 8 of these 16 cases had benefit It was often dramatic with relief of headache and papillœdema, though most relapsed after three or four years Such a relief is surely worth achieving

The results are summarised in tables I and II

Illustrative Cases

Case 1 —The right kidney was tapped in 1933 and no further deterioration was observed on that side for over 11 years, but the left kidney continued to deteriorate and was tapped in 1944 The patient is alive and well 23 years after the first operation

Case 2 —A woman of 26 had her right kidney operated on in 1937 The preoperative X rays report reads "Gross enlargement lower pole of right kidney Pelvis and calyces displaced upwards and stretched over this swelling Ureter displaced inwards General excretion rate is good"

Intravenous pyelography was repeated in 1956, and Dr Blewett, who did not know the history, reported "Both kidneys are secreting a good concentration but the pelves were not completely filled Both are large and, so far as is shown, the outline of the left is consistent with a large cyst polycystic kidney The right one, although the pelvis is large, shows no characteristic cystic impression but may be of a small cyst type" In other words, the radiologist could not be sure that the right kidney (on which we had operated) was cystic, whereas the untreated left kidney was enormous

Clinically the right kidney (which was tapped) is only just palpable, whereas the left is very large and knobbly This supports the suggestion that the tapped cysts do not re form

Case 11 —A priest, aged 43, was in extreme hypertensive heart failure in 1951 His blood pressure was 205/120 mm Hg and his blood urea 58 mg per 100 ml A bilateral Rovsing operation was performed as a life saving measure A month later his blood pressure was 156/104 and the blood urea 28 mg

Atrial fibrillation ceased and he went back to work There was some relapse by 1953 blood pressure 180/120, blood-urea 78 mg A further tapping of the left side allowed another return to work He relapsed again in 1956 and died in uræmia There is no doubt that this patient's life was usefully prolonged for five years

DISCUSSION

Some benefit from cyst-puncture can be expected for various symptoms

Hypertension —There is a quite remarkable fall in blood-pressure, which relieves hypertensive heart-failure and may persist for some years, it is impossible to anticipate which cases will improve, but on the whole the higher the blood-pressure, the more likely the improvement

Pain may be relieved by considerable reduction in the size of the vast swellings, several pints of fluid being removed

TABLE I—PATIENTS AGED OVER 30

Hæmaturia is relieved in some cases

Psychological benefit may be considerable in that at least some treatment is being tried

Renal Function—Deterioration may be prevented, especially in young patients, if the tapped cysts fail to regrow, for it takes some years for the tiny untapped cysts to grow big enough to press on the functioning tissue and damage it Improvement probably derives from removal of pressure on the secreting tissue

Nearly all cases, however, show some immediate post operative deterioration of function I have always attributed this to falling blood-pressure from shock, anæmia, absorption of toxic matter, infection, or even œdema (from the trauma of tapping) temporarily increasing the pressure on surviving nephrons However, Patton and Bricker (1954), found evidence that cystic nephrons may serve as functioning units I have seen (case 17) fluid under great pressure in the cysts in a patient thought to have obstruction due to a ureteric stone, which may be evidence that they were secreting urine Damage to these cystic but functioning nephrons must therefore be justified by at least comparable relief to the normal renal parenchyma

From this and my own experience, I feel sure that it is unjustifiable to operate on both kidneys simultaneously

Late uræmic cases benefit least, the risk of the operation is greater and relief is likely to be short lived In patients without uræmia, however, the prevention of deterioration is, in my opinion, most valuable Young patients seem to do best The one young patient who has died, delayed her operation from 1938 until 1948, and although she had great benefit and lived a full life until her death in 1951, I feel sure that if she had had the operation 10 years earlier, before the blood-urea reached 84, she would have had more kidney tissue to preserve and would have been alive today It is interesting to note that all the patients under 30 were female 4 of them were discovered at antenatal clinics, and the 5th presented with malignant hypertension

No case of polycystic disease in infancy is included, the process is so advanced that expectation of life is negligible In my opinion this disease may have a different pathology

It is hoped that this brief account will stimulate interest in the operation and encourage practitioners to recommend surgery for patients with polycystic disease early enough for them to benefit

Summary

18 patients have had Rovsing's operation Apart from 2 who died soon after operation, all patients have had benefit in one way or another

Expectation of life may be increased when operation is undertaken early In 2 patients benefit from unilateral tapping was compared with the contralateral deterioration after 11 and 19 years respectively Relief from pain and hæmaturia and temporary relief of hypertension can be expected

Renal function is always lowered for a short time, after recovery it is unlikely to improve further, but deterioration is delayed The delay is most marked when there is most kidney to preserve This is an important feature in patients treated early, who are the ones most likely to benefit

EFFECTS OF SOME ANALGESIC DRUGS USED IN CHILDBIRTH

WITH SPECIAL REFERENCE TO VARIATION IN RESPIRATORY-MINUTE VOLUME OF THE NEWBORN

THE comparative inaccessibility of the fœtus prevents detailed observation of the effects on it of analgesics given to the mother during labour, but the respiratory centre of the fœtus in utero is very susceptible to the depressant action of pain relieving drugs, and this depression may be obvious in the infant at birth Many studies have been made of the anoxic newborn, and the degrees of asphyxia classified Nevertheless, we felt that a more detailed investigation of the reactions of the newborn infant's respiratory system to frequently used analgesics would be worth while

Preliminary Survey

A preliminary study was made of alteration in the respiratory minute volume of the newborn infant in response to various analgesics administered to the mother during labour The minute volume was recorded with a trip spirometer described by Donald and Lord (1953) Since an apparatus involving the use of a face mask can annoy and stimulate an infant and promote accumulation of carbon dioxide beneath the mask, the recordings considered were those made by quiet infants over a period of not more than a minute and a half The minute volumes obtained in this series were larger than those recorded by Cross (1949) with a plethysmograph but our results were intended as a measure of comparison and not a physiological standard

During the preliminary investigation the newborn infants were divided into ten groups according to combinations of drugs given to the mother during labour Table I shows the variation of mean minute volumes according to the type of analgesia used The four smallest minute volumes followed the administration of pethidine, but other factors, particularly age and weight, may affect the minute volume and, if the babies had been

TABLE I—MEAN MINUTE VOLUMES IN RELATION TO TYPES OF ANALGESIC

Type of analgesia	No of infants	Mean minute vol (c cm)	S D	S E M
Pethidine	15	893 7	101 2	104
Peth gas air	205	907 2	315 8	21 2
Peth scop gas air	34	1014 4	284 6	48 8
Peth gas oxygen	7	1024 0	381 5	144 2
Peth trichloroethylene	20	1150 5	562 7	125 8
Controls	38	1092 8	401 6	74 9
Gas air	565	1111 8	419 9	17 7
Iso propyl chloride	9	1370 2	328 2	109 4
Gas oxygen	7	1137 6	441 6	166 9
Trichloroethylene	24	1198 7	287 3	58 6

S D, standard deviation   S E M, standard error of mean selected in some way, could be the cause of the apparent effect of pethidine

Each of these four groups was therefore divided into sixteen subgroups—four age-groups and four weight-groups less than 6½ lb , 6½–7½ lb , 7½–8½ lb , and more than 8½ lb

In the gas-and-air group (565 cases) was found a significant increase, apparently linear, of the minute volume with greater body-weight This increase was estimated at 124 9 c cm for each 1 lb increase of weight and was the same for each age-group

To compare the groups, the observations were corrected to 7½ lb (the mean body-weight in the gas-and-air group), the value of 124 9 c cm being used for each 1 lb increase of body-weight The mean values of the corrected figures for each age-group in six of the groups are shown in table II

An analysis of variance showed that the difference in the mean minute volumes of the pethidine and non-pethidine groups was statistically significant at the 1% level The other factors showed no significance We may therefore conclude that pethidine has a depressant effect on the minute volume of the newborn infant The amount of the decrease in minute volume when pethidine is used appears to be about 10–15% and is being examined further

TABLE II—MEAN MINUTE VOLUMES (C CM) BY AGE GROUPS AND ANALGESICS

Levallorphan

Since pethidine appears to diminish the minute volume, it was suggested that an antagonist to it might be used with advantage, therefore the effects of levallorphan with pethidine were studied

Levallorphan tartrate or (—) 3-hydroxy-N-allylmorphinan tartrate differs chemically from levorphan tartrate or (—) 3-hydroxy-N-methylmorphinan tartrate only by the substitution of an allyl group for the methyl group at the nitrogen atom Whereas levorphan exerts an analgesic action like that of morphine levallorphan does not, nor does it behave in other respects like morphine In small doses (0 5–1 0 mg) levallorphan relieves respiratory depression Large doses are required to inhibit other typical effects of morphine, including analgesia The following points require special consideration when it is used during labour (1) its prophylactic value against depression of respiration in the newborn , (2) its effects on other central side effects of drugs of the morphine group (i e , nausea and vomiting) , and (3) its effects on the degree of analgesia The dosage proposed by American workers, after research on animals and some preliminary work on man, is 1 mg of levallorphan to 200 mg of pethidine

Preliminary trials to establish whether levallorphan diminished the analgesia produced by pethidine involved 19 deliveries in two groups of alternate treatments

Group 1 the mother received pethidine only , and levallorphan was given to the infant if asphyxiated

Group 2 pethidine was given when required and about an hour before delivery levallorphan was injected intramuscularly After three or four cases levallorphan was given three quarters to one hour after pethidine In no case did the analgesia appear to be impaired by the levallorphan.

TABLE III—DEGREE OF ANALGESIA ACCORDING TO MOTHERS AND OBSERVERS OPINIONS

Group	Degree of analgesia		
	Very good	Good	Fair
1	3 (*30%*)	7 (*70%*)	0
2	4 (*44%*)	4 (*44%*)	1 (*11%*)

Sufficient pethidine (150–400 mg) was given to promote a very satisfactory analgesia, and the distribution was fairly even in both groups, as was the time relationship to delivery. Gas-and-air was given to the mother as required The degree of relief was judged during labour, immediately after delivery, and again on the following day (table III)

There were 8 (80%) anoxic infants in group 1 and 2 (22%) in group 2, the difference being significant at the 5% level 5 in group 1 responded without levallorphan The remaining 3 were severely affected but responded within a half to one minute after the injection of levallorphan 0 25 mg into the umbilical vein , they became active and cried within two minutes and showed no tendency to relapse The anoxic infants in group 2 responded to minimal treatment

This pilot experiment helped in the planning of the main survey It will be seen that the patients studied in the pilot experiment received larger doses of pethidine

Main Survey

508 cases were studied Three groups were established

Group A pethidine and gas-and-air (177 cases)

Group B pethidine, levallorphan, and gas and air (178 cases)

Group C methylpentynol ('Oblivon ') and gas and air (120 cases) Subgroup C2 was created by patients who required pethidine in addition to methylpentynol (33 cases)

The administration of the various drugs, according to a table of random numbers, was as follows :

Group A intramuscular pethidine 150 mg initially and 100 mg when required , gas and air when required

Group B pethidine 150 mg and levallorphan 1 mg given in the same syringe Subsequent doses were pethidine 100 mg. and levallorphan 0 5 mg Gas and air as in group A

Group C Oblivon elixir ' 6 drachms orally with water If the patient vomited within ten minutes, draught was repeated immediately Subsequent doses of 3 or 6 drachms as required Gas and air was administered In 33 cases pethidine 150 mg was given

Groups A and B are reviewed together (table IV) and group C separately

GROUPS A AND B

Anoxia in Newborn

There were 6 severely anoxic newborn infants in group A All were subjected to endotracheal intubation

TABLE IV—TYPES OF DELIVERIES INCIDENCE OF ANOXIA IN NEWBORN, AND RELIEF OF PAIN

—	Group A		Group B	
	Primigravidæ	Multiparæ	Primigravidæ	Multiparæ
Deliveries	78	99	83	95
Normal deliveries	65	97	83	95
Forceps deliveries	11 (*14%*)	1 (*1%*)	5 (*6%*)	0
Cæsarean sections	2 (*2 5%*)	1 (*1%*)	0	0
Postmaturity	9 (*11 5%*)	13 (*13%*)	3 (*3 6%*)	15 (*15 8%*)
Prematurity	9 (*11 5%*)	5 (*5%*)	5 (*6%*)	5 (*5 2%*)
Anoxia at birth				
Severe	2 (*2 5%*)	4 (*4 1%*)	0	0
Moderate	4 (*5 0%*)	6 (*6%*)	6 (*7 2%*)	1 (*1 1%*)
Mild	8 (*10%*)	3 (*3%*)	10 (*12%*)	5 (*5 2%*)
Stillbirth	1 (*1%*)	0	0	0
Relief from pain				
Good	124 (*70%*)		134 (*75 2%*)	
Fair	42 (*23 7%*)		36 (*20 2%*)	
Poor	8 (*4 5%*)		8 (*4 4%*)	

Abnormal factors associated with the delivery were cæsarean section, forceps delivery in 2 cases, and prematurity in 1 infant In the moderately affected infants such complications as cæsarean section, forceps delivery, cord tight round the neck, and antepartum hæmorrhage occurred in equal proportions in both groups

It is difficult to assess relief of pain, because the personal element interferes with impartial judgment But by having only one person to question patients the day after their deliveries, one can estimate fairly consistently the degree of analgesia produced by pethidine and by pethidine with levallorphan (table IV) Group B showed slightly more analgesia, which fact, though possibly not significant, confirms that levallorphan 1 mg to pethidine 150 mg did not impair the analgesic value of the pethidine Some of the nurses said that levallorphan appeared to make the patient drowsier

TABLE V—INCIDENCE OF ANOXIA IN RELATION TO TIME OF ADMINISTRATION OF PETHIDINE

Time of giving single dose of pethidine 150 mg	No of deliveries	No of anoxic infants
Group A		
Within 3¹/₄ hr of delivery	107	10 (*9 3 %*)
More than 3¹/₄ hr before delivery	49	11 (*22 4 %*)
Group B		
Within 3¹/₄ hr of delivery	104	9 (*8 6 %*)
More than 3¹/₄ hr before delivery	42	7 (*16 6 %*)

The distribution of the amount of pethidine in the two groups did not differ much

The higher incidence of anoxia in the infants was in the group where the mother received the pethidine more than three and a quarter hours before delivery (table V), which fact is rather unexpected These cases were uncomplicated by anæsthesia, and only a mixture of nitrous oxide and air was given in addition to the pethidine

Minute Volume of Newborn

Satisfactory records were made of the minute volumes of 419 newborn infants in six groups according to the analgesics received by the mother during labour Delivery was uncomplicated by anæsthesia, and the three-and-a-quarter hour limit is purely arbitrary The groups are as follows

A1 pethidine (P), last dose less than three and a quarter hours before delivery

A2 pethidine (P), last dose more than three and a quarter hours before delivery

B1 pethidine and levallorphan (P L) less than three and a quarter hours before delivery

B2 pethidine and levallorphan (P L), last dose more than three and a quarter hours before delivery

C1 methylpentynol (M)

C2 methylpentynol and pethidine (M P)

The age distribution was about the same in each group

The mean weight of all the babies whose minute volumes were recorded was 7 34 lb , the mean weights in each group being as follows

A1 (P)	A2 (P)	B1 (P L)	B2 (P L)	C1 (M)	C2 (M P)
7 27	7 57	7 22	7 48	7 44	7 10

Thus the groups are comparable for age and weight, and we may therefore compare their minute volumes

In any one group the distribution of minute volumes was decidedly skew, so the groups are probably best compared by using the logarithms of the minute volumes instead of the actual volumes The accompanying figure shows the distribution of the minute volumes on a logarithmic scale in each group, there are no great differences in the distributions, although perhaps there may be a difference between the groups C1 and C2

Table VI gives the mean logarithm of the minute volumes of each group and the geometric mean of the minute volumes (The geometric mean is the antilog of the mean logarithm of minute volumes) The geometric mean cannot be compared with the more usual arithmetic mean but is probably more useful in the present case as a measure of the middle minute volume of each group, as roughly half the babies have minute volumes greater than the geometric mean, and half less

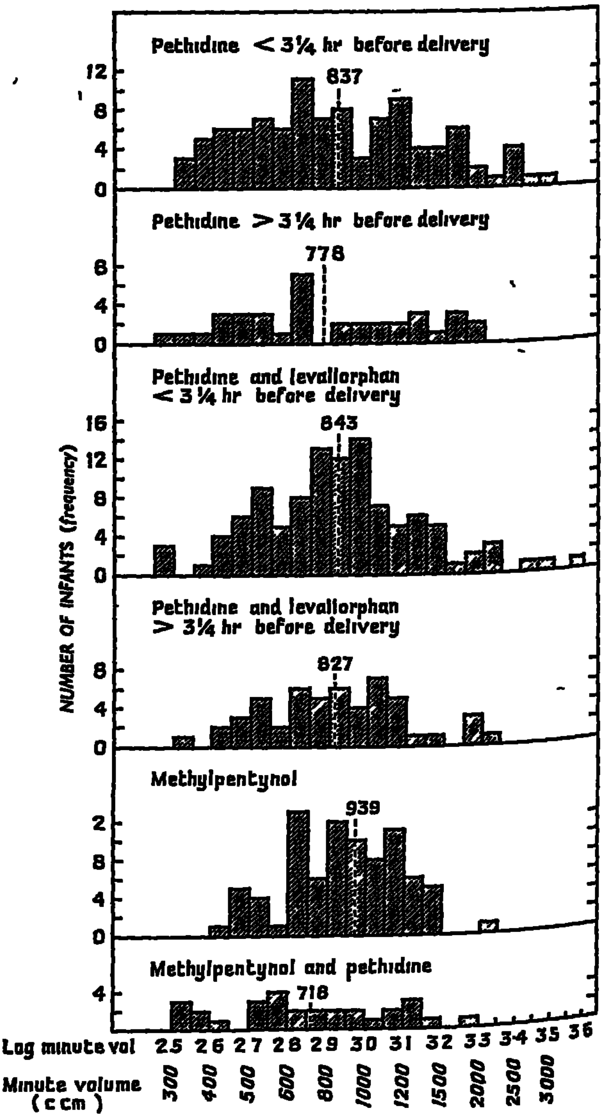
TABLE VI—MEAN LOGARITHMS AND GEOMETRIC MEANS OF MINUTE VOLUMES BY TYPE OF ANALGESIC

Group	A1 (P)	A2 (P)	B1 (P L)	B2 (P L)	C1 (M)	C2 (MP)
Mean log	2 923	2 891	2 926	2 917	2 973	2 856
Geometric mean	837	778	843	827	939	718

Although the groups are comparable for age and weight and the minute volumes can thus be compared without correcting for these factors, it is of interest to examine their effects

The actual minute volume is used here, rather than the log minute volume as in the previous section, because, although the logarithm is better on statistical grounds, the actual minute volume enables comparison to be made with previous work

The relationship between the minute volume and body-weight was found for each group and each age



Distribution of minute volumes of newborn infants on logarithmic scale (geometric mean given) group, the mean increase of minute volume being 118.2 c.cm. for each increase of 1 lb. in weight. This compares with 124.9 c.cm. found from 565 babies in a previous survey, the difference being insignificant.

The mean minute volumes (corrected for weight) for each group and age-group are given in table VII.

TABLE VII—MEAN MINUTE VOLUME CORRECTED FOR WEIGHT FOR EACH ANALGESIC GROUP AND AGE GROUP

Age (hr.)	Mean minute volume (c.cm.) (corrected for weight)					
	A1 (P.)	A2 (P.)	B1 (P.L.)	B2 (P.L.)	C1 (M.)	C2 (M.P.)
0–1	1147	1089	1013	1007	1072	1010
1–2	946	910	1055	764	1047	803
2–3	812	564	836	733	853	589
3–4	595	802	721	651	694	367
4–10	805	646	793	828	998	527
1–10	818	740	916	771	907	676

Approximate analyses of variance of groups A and B in table VII show:

(1) There is no evidence that, when pethidine is used, the addition of levallorphan has any effect on the minute volume.

(2) There is a significant difference between the minute volumes at different ages. The data suggest that the minute volume is high immediately after birth, declining to a minimum at about three to four hours, and thereafter increasing.

Methylpentynol

The use of methylpentynol in labour has been studied clinically by Bourne (1954). Our observations agree with his conclusion that it diminishes the stress of labour.

Methylpentynol is highly selective in its action, relieving apprehension and acting as a sedative but exerting no antispasmodic or analgesic action. In cases of overdosage both nikethamide and methylamphetamine hydrochloride given intravenously have proved to be satisfactory restoratives. Experiments on rats have shown that about 20% of the methylpentynol given was in adipose, muscle, and liver tissue while the rats were still under its hypnotic influence. No residual products were found in the tissues when the clinical effects had worn off. Methylpentynol is not incompatible with any other drug. When it is given with barbiturates, there is a summation of the effects of both drugs.

GROUP C

The results obtained in group C are set out in table VIII. The pethidine 150 mg. in group C2 was given when the mother appeared to need more relief than the methylpentynol and gas and air sequence would produce.

The incidence of analgesia and some side effects produced by methylpentynol alone on the mother were as follows:

Relief from pain		
Good	*Fair*	*Poor*
38 (31.0%)	37 (30.8%)	45 (37.5%)

Drowsiness	48 (40.0%)
Euphoria	34 (28.0%)
Amnesia	4 (3.3%)
Dizziness	2 (1.6%)
Vomiting within 10 minutes of receiving drug	11 (9.1%)

Methylpentynol given in early labour appeared to accentuate the analgesic effect of pethidine and of gas-and-air given at a later stage of labour.

In group C1 the anoxia in 2 newborn infants was associated with a forceps delivery for persistent occipito-posterior presentation and with a premature infant weighing 2 lb.

The infants with mild anoxia in group C1 recovered with the minimum of extra attention.

The stillbirth in group C1 is difficult to explain, because the fœtal heart sounds disappeared about fifteen minutes before delivery, more than two hours after the administration of 6 drachms of methylpentynol. Since methylpentynol is excreted in about an hour it is unlikely to have played any part in the death of the fœtus.

Comparison of the minute volumes in groups C1 and C2 in table VIII shows that the mean minute volume in the group where pethidine was used was significantly smaller than in the group where pethidine was not used.

Conclusions

Comparisons of the minute volumes of newborn infants indicate that pethidine given to the mother during labour leads to diminished respiratory activity in the baby for some hours after birth.

The levallorphan-pethidine and pethidine groups in the main survey showed no statistical significant difference between the minute volumes in the two groups.

The effect of the levallorphan was more noticeable in the pilot experiment, where the amounts of pethidine given to the mothers were greater than in the main survey, and the incidence of anoxia in the newborn was less in the levallorphan-pethidine group; here the difference is significant at the 5% level.

We suggest that, if similar doses of pethidine had been given in the larger trial, the value of the levallorphan would have been reflected in larger minute volumes of the infants in the levallorphan-pethidine group. Alternatively, an increase in the amount of levallorphan per 200 mg. of pethidine might have produced more positive results. Levallorphan does not diminish the analgesic effect of pethidine, and clinical observations show that it may enhance the sedation produced by pethidine.

Methylpentynol appears to have only a moderately depressant effect on the minute volume, compared with the gas-and-air group in table II. It can be concluded that methylpentynol can be of value during labour to produce a sense of relaxation and drowsiness in a small proportion of cases (about 40% of those reviewed here) and to augment the analgesic action of other drugs given later in labour.

TABLE VIII—RESULTS IN MOTHERS GIVEN METHYLPENTYNOL AND THOSE GIVEN METHYLPENTYNOL AND PETHIDINE

—	Group C1 (methylpentynol)		Group C2 (methylpentynol and pethidine)	
	Primigravidæ	Multiparæ	Primigravidæ	Multiparæ

Fair	30 (25.0%)		7 (21.2%)	
Poor	10 (8.3%)		2 (6.1%)	

Summary

The alteration in the minute volume of the newborn in response to various analgesics administered to the mother during labour was studied.

The mean minute volume of 565 newborn infants in the gas-and-air group was compared with that of 205 babies in the pethidine/gas-and-air group. Pethidine apparently reduced the volume by 10–15%.

The action of levallorphan as an antagonist to pethidine was studied. The mean minute volume of 177 newborn babies of the pethidine/gas-and-air group was compared with that of 178 infants of the pethidine/levallorphan/gas-and-air group. There was no significant increase in the mean minute volume in the latter group.

Methylpentynol was administered to 153 patients in labour: 120 receiving methylpentynol and gas and air, and 33 methylpentynol, pethidine, and gas and air. Of the former group 66.6% experienced satisfactory relief, of the latter 72.7%. The mean minute volume of the newborn infants in the group in which pethidine was used was significantly lower than in the methylpentynol/gas-and air group

We wish to thank Prof McClure Browne, the board of governors of the Hammersmith, West London, and St Mark's Hospitals, and the matron of Hammersmith Hospital for their interest and cooperation, and the midwifery staff of the labour ward for their help during the trials Prof Ian Donald helped immeasurably by lending the trip spirometer for which we are most grateful to him Roche Products Ltd supplied the levallorphan, and British Schering Ltd the 'Oblivon' Finally, we wish to acknowledge with gratitude the monetary help given to one of us (H R) by the National Birthday Trust Fund, without whose assistance this work could not have been done

INHIBITION OF GASTRIC EMPTYING AND SECRETION IN PATIENTS WITH DUODENAL ULCER

J N HUNT
M D, D Sc Lond
READER IN PHYSIOLOGY, GUY'S HOSPITAL MEDICAL SCHOOL, LONDON

GASTRIC hypersecretion of acid and pepsin is common in patients with duodenal ulcer, and there is a strong tradition that such patients often show unduly rapid gastric emptying (Hurst and Stewart 1929) I report here experiments designed to determine whether failure of one of the mechanisms which normally inhibit gastric activity can explain part or all of the gastric hyperfunction in patients with duodenal ulcers

Although the plan of the experiments is simple it is best explained in terms of a concrete example Suppose that, under conditions which produce minimal inhibition of gastric emptying, subject A empties 400 ml of a test-meal from his stomach whereas subject B empties only 200 ml, and that, on retesting these subjects with a meal which powerfully inhibits gastric emptying, subject A empties 100 ml and subject B also empties 100 ml It may reasonably be concluded that subject A has the more effective inhibitory mechanism braking gastric emptying, and that the ratio of the uninhibited rate of emptying to the inhibited rate may be used to assess the degree of its effectiveness

Earlier experiments had shown that a saline solution containing 100 m eq of sodium chloride per litre left the stomach very rapidly and could be regarded as a minimal stimulus to the duodenal osmoreceptors whose activity slows gastric emptying (Hunt 1956) To provide an index of the rate of minimally inhibited gastric emptying such a test-meal was used In the second test a solution containing 100 g of glucose per litre provided a powerful stimulus to the duodenal osmoreceptors which slow gastric emptying Gastric secretion is usually inhibited by the same conditions as inhibit emptying, therefore a comparison of the ratios of the secretory responses to these two meals was also used to assess the effectiveness of the mechanism inhibiting gastric secretion

The work described here leads to the conclusion that rapid gastric emptying is not generally characteristic of patients with duodenal ulcer, but that such patients do, in response to test-meals, secrete about twice as much acid and pepsin as do healthy persons The mechanism which inhibits gastric secretion and emptying in response to glucose has not been found to be defective in patients with duodenal ulcer

Methods

Control studies were made on 27 healthy students The patients with a diagnosis of duodenal ulcer without pyloric stenosis were under treatment in the medical and surgical wards of the hospital After the stomach had been washed out, two test-meals were given by tube on separate days one of 750 ml of saline solution containing 100 m eq of sodium chloride per litre, and one of 750 ml of glucose solution (100 g per litre), both of which contained the dye phenol red as a marker Ten minutes after the saline solution was given and thirty minutes after the glucose solution was given, the whole of the gastric contents was recovered The concentrations of phenol red, acid, chloride, and pepsin were determined in the recovered gastric contents From these data and corresponding data on the meal before ingestion the amounts of acid, chloride, and pepsin secreted were calculated (Hunt 1954) The data for the test-meals containing glucose have already been reported as a control for studies on the influence of hydrochloric acid on gastric secretion and emptying in 16 patients (Hunt 1957) Because there was a technical failure in estimating the secretory response to one of the saline meals, comparisons of secretion are based in this paper on 17 tests in 15 patients with duodenal ulcer

TABLE I—MEAN VOLUMES OF MEAL AND OF GASTRIC CONTENTS AFTER TEST MEALS OF SALINE AND OF GLUCOSE SOLUTION

—	27 healthy people	16 patients with duodenal ulcer (18 tests)
Volume of gastric contents 10 min after saline meal (ml)	408 ±29	370 ±31
Volume of saline meal remaining at 10 min (ml)	361 ±27	322 ±26
Volume of gastric contents at 30 min after glucose solution (ml)	566 ± 9	542 ±21
Volume of glucose solution remaining at 30 min (ml)	489 ± 9	439 ±23

The figures after the means are the standard errors of the means

Results

Gastric Emptying

Table I shows that there is no significant difference between the healthy people and the patients with duodenal ulcers in their rate of gastric emptying of saline meals If gastric emptying of glucose solution is assessed from the mean data for volume of gastric contents remaining at thirty minutes, there is no significant difference between the healthy people and the patients with duodenal ulcers The table also shows that the patients with duodenal ulcer had a mean volume of meal remaining in the stomach 50 ml less than that found in the healthy people, but this difference is too small to be considered clinically significant

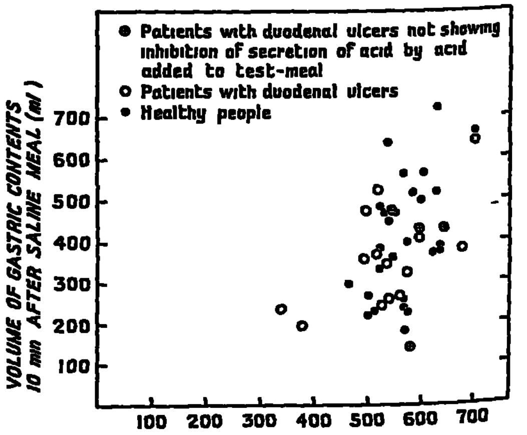

Fig I—Relation between volume of gastric contents 10 minutes after a saline meal and 30 minutes after a meal of glucose solution (100 g per litre)

The data on gastric emptying are given in more detail in fig 1, in which the individual values for the volumes of the gastric contents with saline meals have been plotted against the corresponding values for the volumes of gastric contents with meals containing glucose. It will be seen that the points for the patients and the healthy people are freely intermixed. Moreover, the high standard error of the mean volume of the gastric contents for the patients with duodenal ulcer after the meal of glucose solution will be seen to be largely attributable to two points.

It may be concluded that a duodenal ulcer is not associated with any characteristic emptying of these test-meals. There is no evidence of general defective operation of the duodenal brake in patients with ulcer which would have been indicated in fig 1 by the points for patients with duodenal ulcers lying to the left of those for healthy people.

Gastric Secretion

The mean data on the gastric secretion for two test-meals are shown in table II, which shows that, although in response to both types of meal the patients with duodenal ulcer secreted about twice as much acid, chloride, and pepsin as did the normal subjects, the ratios of the mean response to meals containing glucose to the mean response to saline meals are nearly equal for the healthy people and the patients with duodenal ulcers.

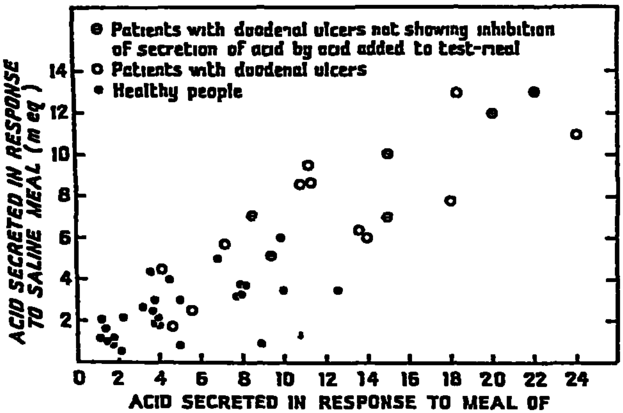

Fig 2—Relation between secretory response to saline meal in 10 minutes and to a meal of glucose (100 g per litre) in 30 minutes

The data on the secretion of acid are given in more detail in fig 2, in which the amount of acid secreted in response to the meal containing glucose has been plotted against the amount of acid secreted with the saline meal for each person.

Although many of the patients with duodenal ulcers secreted more acid than did the healthy people, there is nothing to suggest that, relative to their response to saline meals, the patients secreted more acid in response to solutions of glucose than did the healthy people. 6 of these patients were found not to respond to the addition of hydrochloric acid to test meals by an inhibition of the secretion of acid (Hunt 1957). Their data are specially marked in fig 2 but do not stand out from those of the other people.

It may be tentatively concluded that the two inhibitory mechanisms, that responding to glucose and that responding to acid, have at least one component which is not common—possibly the duodenal receptors.

Because the gastric mucosa produces at least two secretions, one containing acid and the other containing bicarbonate, the measured output of acid is not necessarily a good index of the secretion of acid which is partly neutralised by the bicarbonate of the non-parietal secretions. For this reason the secretory responses are shown in table II in terms of the hypothetical parietal and non-parietal secretions (Hollander 1938, Fisher and Hunt 1950). It will be seen that the data confirm the remainder of table II in that the patients with duodenal ulcers secreted about twice as much parietal component as did the healthy people.

TABLE II—MEAN GASTRIC SECRETION IN RESPONSE TO MEALS OF SALINE AND TO GLUCOSE SOLUTION

—	27 healthy people	15 patients with duodenal ulcer (17 tests)
Outputs in response to saline meal in 10 min		
H⁺ (m eq)	2.6 ± 0.3	6.8 ± 0.8
Cl⁻ (m eq)	7.8 ± 0.5	13.2 ± 1.5
Pepsin (units)	3600 ± 250	8000 ± 1700
Parietal component (ml.)	25.4 ± 1.8	50.6 ± 5.3
Non parietal secretions (ml)	30.0 ± 2.0	34.2 ± 5.7
Outputs in response to meal of glucose solution in 30 min		
H⁺ (m.eq)	5.1 ± 0.6	12.5 ± 1.7
Cl⁻ (m.eq)	8.4 ± 0.7	19.1 ± 2.0
Pepsin (units)	6300 ± 870	11 400 ± 2000
Parietal component (ml.)	36.7 ± 3.8	87.8 ± 11.7
Non parietal secretions (ml)	18.5 ± 1.8	35.8 ± 3.4

The figures after the means are the standard errors of the means

Discussion

The maximal emptying power of the stomach in healthy people and patients with duodenal ulcers without stenosis has been assessed by using test-meals of saline solution which empty very rapidly (Hunt 1956). There is nothing in the data obtained to establish that the maximal emptying power is greater in the patients than in the healthy people.

As an alternative cause of the rapid gastric emptying which is believed to be common in patients with duodenal ulcer, it might be suggested that the power of the duodenal mechanism which slows gastric emptying may be defective, but it has not been possible to demonstrate this with glucose or with acid (Hunt 1957) as the stimulus to the duodenal brake.

It is not surprising that a cause of rapid gastric emptying in patients with duodenal ulcer has not been discovered, because it has not even been possible to demonstrate that rapid gastric emptying is specially common in such patients. This finding is confirmed by Brooks et al (1950), in whose experiments the volume of the saline test-meal was 100 ml compared with 750 ml in the present experiments. Hence it appears that the failure to demonstrate rapid gastric emptying with these two meals of widely different type in patients with duodenal ulcer cannot be explained as arising from the use of an unsuitable volume of meal.

The absence of any convincing evidence of abnormal gastric emptying stands in striking contrast to the gastric hypersecretion found in the patients with duodenal ulcer in response to saline meals and to meals containing glucose. However, the hypersecretion cannot be explained by any defect in the inhibitory mechanism which responds to glucose, although such a failure has been demonstrated in response to acid added to test-meals in 6 of these 16 patients (Hunt 1957). This latter finding clearly suggests that the inhibitory mechanisms operated by acid and glucose are separable.

It seems probable that the hypersecretion of acid and pepsin by patients with duodenal ulcer can be largely explained by an increased number of parietal and peptic cells in the stomachs of such patients (Guiss and Stewart 1948, Meyers 1948, Hunt 1950, Card 1952, Cox 1952, Hunt and Kay 1954). This conclusion should direct attention to the importance of the tonic action of the vagus in maintaining the integrity of the mucosa (Oberhelman and Dragstedt 1948), because vagotomy decreased the secretory response to histamine which is currently believed to act on the parietal cells.

The anterior lobe of the pituitary gland (Kyle and Welbourn 1956) may also influence the population of cells, because there is pronounced gastric hyposecretion in patients with atrophy of the pituitary gland

There is also, in some patients with duodenal ulcer, a deficiency in the mechanism which reduces gastric secretion in response to a rising acidity of the gastric contents (Shay 1944, Hunt 1957), the receptors mainly operating from the duodenum but also possibly from the antrum (Woodward et al 1954)

Summary

Saline test-meals and test-meals containing glucose were given to 27 healthy people and 16 male patients with duodenal ulcer

There was no convincing evidence of unduly rapid emptying of either of these meals by the patients with duodenal ulcer

The secretory response to these two test-meals (measured as amounts of acid, chloride, and pepsin) by patients with duodenal ulcer was about twice that of the healthy people

In patients with duodenal ulcer there was no evidence of any abnormality in the mechanism which regulates gastric emptying and secretion in response to changes in the osmotic pressure of the duodenal contents produced by glucose

It is a pleasure to thank many clinical colleagues for permission to investigate their patients with duodenal ulcers, the patients themselves, and the students who cooperated in these studies I am indebted to the Society of Apothecaries for the award of the Gillson scholarship, out of which part of the expenses of this research were defrayed

MANUAL ARTIFICIAL RESPIRATION IN THE SITTING POSTURE

Henning Ruben

Cand Med Copenhagen

DIRECTOR, DEPARTMENT OF ANÆSTHESIA, FINSEN INSTITUTE, COPENHAGEN

If a patient stops breathing while sitting in a chair (e g , at the dentist's), it is necessary to move the patient from the chair to the floor to apply any of the current methods of artificial respiration This may cause injury and loses valuable time It is also possible that a person might stop breathing in a confined space without any possibility of lying down in an extended position—e g , in railway accidents and in bombed buildings

A new method of manual artificial respiration has therefore been devised for treating apnoeic patients in the sitting posture

Technique

Both inspiration and expiration are actively produced by this method by the operator stationed either in front of or beside the patient

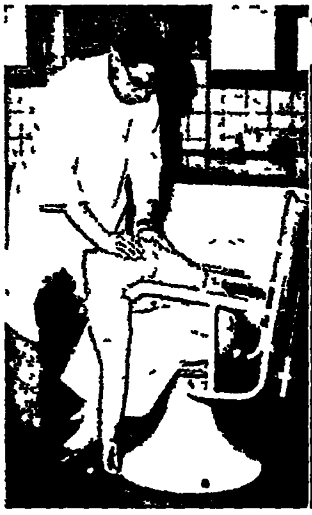

Fig 1—Expiration

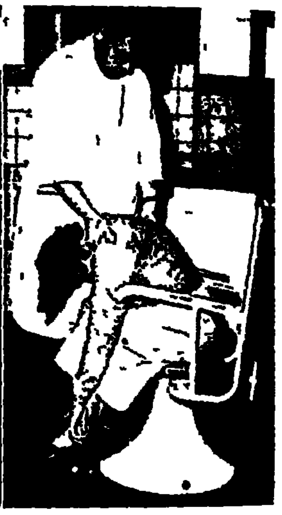

Fig 2—Inspiration

Expiration

The patient's body is flexed in such a way as to bring the head and trunk close to the legs The flexion is increased by pressing on the patient's back (figs 1 and 3) This manœuvre both compresses the abdominal contents, thus forcing the diaphragm upwards, and decreases the capacity of the thorax

Inspiration

The operator stops pressing on the back, so that the thorax will expand passively and reach its resting position, in which inspiration starts Inspiration is increased by lifting the upper part of the body, thereby decompressing the abdominal contents and allowing the diaphragm to descend

The method of lifting the upper part of the body depends on the position of the operator An operator standing in front of the patient can lift the upper part of the body by placing his hands one in front of each shoulder An operator standing to the right of the patient can lift the upper part of the body by placing his right hand on the patient's left shoulder and his left hand in the patient's right axilla (figs 2 and 4)

If the lifting is done in such a way that the patient's spine is extended slightly, the depth of inspiration will be increased by the resulting increase in the capacity of the thorax

Artificial expiration and inspiration are applied thus alternately about 12–15 times a minute

Experimental Trial

In 6 patients who underwent an operation under general anæsthesia, and who gave permission for special investigations to be made, the tidal air produced by this method of artificial respiration was measured immediately after the operation During the application of the method the patients respired atmospheric air not enriched with oxygen All the patients were endotracheally intubated, and an airtight fit between the catheter and the trachea was ensured by the use of an inflated cuff The free end of the tube was so connected that the inspired air and the expired air were kept separate The expired air was passed through a gas meter, with which it was possible to measure the tidal air with an accuracy within at least 50 c cm

The apnœa was produced by intravenous suxamethonium iodide, and the application of artificial respiration was interrupted several times to make sure that apnœa was still present Usually, 75 mg of suxamethonium iodide was sufficient to induce apnœa, and 15–30 mg a minute to maintain it, and the trials usually lasted 10–15 minutes on each person

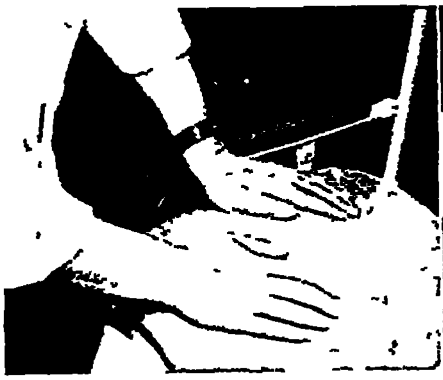

Fig 3—Expiration

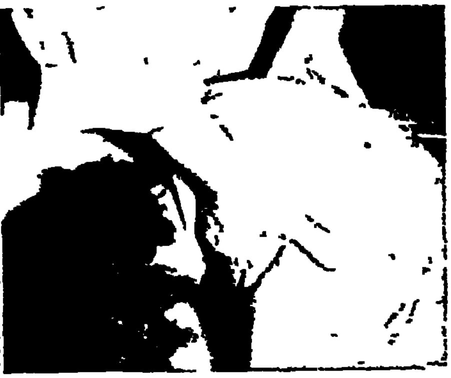

Fig 4—Inspiration.

The patients were kept unconscious with intravenous thiopentone No complications occurred, and no patient showed signs of oxygen lack during or after the trial.

During the application of artificial respiration the values of different variations in the method were compared—e g, lifting of both shoulders, lifting of one shoulder alone (with slight rotation of the upper part of the body), "high" compared with "low" lifting of the upper part of the body, no lifting at all (only intermittent pressure on the back being used), flexion of the body with and without pressure from the legs, and the use of two operators instead of only one

The amount of physical effort required by the operator and the technical difficulty in applying the method were also estimated

The results are shown in the accompanying table The air exchange per respiration was 300–1200 c cm, depending on how the method was applied The table shows that the volume of tidal air was about the same as in current methods of artificial respiration applied to patients lying down in an extended position

The air exchange was 500–1000 c cm per respiration when the method was applied by one person alone The air exchange was not significantly increased when two persons simultaneously applied the method Also it did not seem to matter whether, during flexion, pressure from the legs against the thorax was used or not, or to what height the upper part of the body was lifted Lifting the trunk just a little way off the legs seemed to suffice It also seemed to be unimportant how the lifting was done, but lifting both shoulders produced a slightly greater air exchange than lifting one shoulder only

The patients were maximally relaxed (curarised) during the trials so the results were obtained under the most unfavourable conditions for applying manual artificial respiration During apnoea patients often retain some tonicity of the muscles, which might make the air exchange greater and the method more easy to apply, but in any case the method is not particularly tiring to apply

No preparation is required, therefore this method of artificial respiration can be applied immediately There is no technical difficulty in applying it, therefore an untrained onlooker may take over its application without any other training than just watching it being applied for a few seconds

COMPARISON OF METHODS OF ARTIFICIAL RESPIRATION

Case no	Sex	Age (yr)	Body weight (kg)	Height (cm)	Air exchange in different variations of sitting method (c cm)	Average air exchange in standard method (c cm)
1	F	28			800–1000	About 800
2	M	27	67	164	550–1200	" 1000
3	F	44	79	[illegible]	300–700	450
4	F	51	[illegible]	162	300–700	500
5	M	55	60	170	400–1000	650
6	F	11	50	162	450–700	550

The patient's position in this method appears optimal for maintaining the air-way free because the tongue automatically moves forwards, or can easily be made to do so, because any fluid contents of the mouth and the pharynx will move forwards out of the mouth, and because the mouth cannot be obstructed by the application of the method

During the intermittent flexion of the body the abdominal viscera press not only on the diaphragm but also on the vena cava, thus possibly helping to pump the blood towards the heart

Summary

A new method of manual artificial respiration is described

It consists in alternate flexion of the upper part of the body against the knees of the patient and subsequent extension

Experimental trials on curarised patients showed that an effective exchange of air was produced by this method

The patient's position during the application of the method maintains a free air-way and avoids aspiration

The method is very simple and can be learnt in a few seconds

This method of artificial respiration is useful for patients who become apnoeic while sitting (e g, at the dentist's) and where the patient cannot be put lying down in an extended position

REGRESSION OF SECONDARY CARCINOMA AFTER HORMONE THERAPY

C E GOLDSBOROUGH
M B Durh

GENERAL PRACTITIONER, ROTHWELL HAIGH, NEAR LEEDS

THE following cases are presented in the hope that similar trials will be made of the methods outlined They are two cases of cancer, the first of the breast, the second of the œsophagus secondary to an epithelioma of the finger What makes them worth reporting is that case 1 survived for five years despite recurrence of metastases after surgical removal of the primary growth, and case 2 recovered to the extent of being able to drive his car for six months after he had appeared moribund

The method of treatment was evolved after I had treated three previous cases of cancer of the breast which had recurred after surgical removal In two of these cases stilbœstrol 15 mg daily was injected and in the third case testosterone propionate 25 mg daily was injected In all three cases there was some initial regression of secondaries, but all three patients died of diffuse secondaries with ascites I then decided to try, in the next case that presented (case 1), the effect of combining œstrogen with androgen therapy This was given in the form of 'Mixogen' (Organon) tablets These appeared to be more effective than either androgen or œstrogen alone, but their effect was also temporary Injections of gonadotropic hormone—'Pregnyl' (Organon)—were then given and were wholly successful in causing regression of the metastases This patient is alive and well after five and a half years

Case 2 was therefore also treated with pregnyl injections, with the temporary but dramatic improvement already mentioned, the patient being able to swallow solid food again as well as to drive his car

Case-reports

Case 1 —A woman, aged 59, was seen on March 10, 1951, with two months' history of a lump in her right breast I referred her to a surgeon, who described the growth as a late stage II carcinoma and amputated the breast on March 22 Histologically the growth was an intraduct carcinoma which in parts had become frankly scirrhous The wound healed well, and the patient was given a course of intensive deep X rays in the following June, consisting of six daily irradiations There was a severe reaction, with some eczematisation of the chest wall She later developed severe myxœdema The reaction subsided, and she remained well until January, 1952, when she developed severe pain in both thighs and legs, chiefly in the right thigh She was considered to have a secondary deposit and had a further course of six irradiations This did not relieve her pain She had now developed the classical symptoms of deficient eyebrows, swollen and coarsened features, thin hair, and a low pitched croaking voice She was put on thyroid gr $^{1}/_{2}$ t d s, together with stilbœstrol 15 mg t d s At this time her general condition was poor and she had lost weight, was bedfast, vomited not infrequently, and was intolerant of the stilbœstrol, which was reduced to 15 mg daily She was maintained free from pain with either methadone ('Physeptone') or pethidine and was given quinalbarbitone ('Seconal') sodium gr $1^{1}/_{2}$ at night The pain became less with the stilbœstrol for four to six weeks and then began to worsen again

At this time her general condition was poor, and she was totally confined to bed again and was feeble and confused Mixogen 1 tablet t d s was substituted for the stilbœstrol *She held her own rather than improved* After six weeks' treatment with mixogen, in December, 1952, she began to bleed per vaginam fairly heavily, despite her age (61) The tablets of mixogen were reduced to one daily, and she was maintained on these until February, 1953, when she began to complain of severe pain in her right shoulder and neck The posterior fold of the right axilla began to swell and ulcerate, and she developed a typical fungating secondary deposit, which became offensive, requiring daily toilet by the district nurse The patient became disoriented and ran a swinging temperature of 101–102°F at night

It was then that pregnyl injections were begun She was started with 100 rat units daily After two days the dosage was stepped up to 1000 rat units daily and kept at this level for a week The patient appeared to be sick because of the injections, and the dose was reduced to 750 rat units daily At first one mixogen tablet was given daily with the pregnyl, but after a week the pregnyl was given alone At the start of the treatment with pregnyl the patient was considered to be in the final stages of cancer, and morphine analogues were given freely After a month of injections, however, the fungating mass had disappeared The patient has almost complete amnesia for this period The injections were stopped after six weeks Two weeks later she developed a severe pain in the region of the distribution of the 6th and 7th cervical nerves on movement, and the pain became so bad that she was referred to hospital During this time she had a further course of pregnyl injections, which lasted three months At hospital she was fitted with a plastic collar, which she wore for four months The second course of pregnyl consisted of injections of 500 rat units each thrice weekly During this period she steadily gained strength She has had no injections of pregnyl since, and is now very well but has to be maintained on thyroid

Case 2 —A tall spare man, aged 66, who had had chronic bronchitis and emphysema for years His blood pressure was 220/110 For ten years he had had, on the little finger of his right hand, a wart which, after being knocked about August, 1954, broke down and ulcerated He kept a leather finger stall on this wound until, visiting him one day, I questioned him about this bandage, whereupon he displayed the finger, which appeared to have an epithelioma over the knuckle of the first joint I referred him to a dermatologist, who confirmed the diagnosis and, rejecting my suggestion that the finger be amputated, prescribed a radium collar There was, unfortunately, some delay in admitting him to hospital, but he was admitted in October, 1954, treated, and discharged at the beginning of November The local condition apparently healed but almost from the time of his coming home the patient had difficulty in swallowing, and this dysphagia steadily increased until he could take only sips of fluid, and he rapidly wasted and became cachectic His general condition now was poor, he had lost more than a stone in weight and was obviously failing rapidly He had a profound aversion to hospital, and there was *little I could do but call* out a consultant to decide whether he had indeed a carcinoma of the œsophagus This was done, and the patient was taken into hospital for a barium swallow This upset him very much because he could not swallow the barium, which regurgitated, he was also upset by the hospital routine When his wife visited him in hospital she was so upset by his rapidly worsening condition that she insisted on my getting him out of hospital immediately so that he could, as she said, die at home

This was accordingly done, and pregnyl injections were begun immediately Enemas were given to clear his loaded bowel After two weeks of daily injections of 500 rat units he began to swallow more easily, and the nausea lessened On his return from hospital he was so weak that he could scarcely move in bed, his dysphagia was almost complete, and he was incontinent Now he could take a fair amount of fluid in small sips He was given injections of pregnyl 750 rat units thrice weekly, and his capacity to swallow improved until, at the end of a month, he was taking two pints daily of meaty fluids (Armour's peptone, 'Bovril,' and similar fluids) About this *time it seemed reasonable to decide whether or not he* had a carcinoma of the œsophagus, and Mr J A Aylwin was called in consultation to decide whether it was possible to pass an œsophagoscope Since the patient resolutely refused to become an inpatient, Mr Aylwin took him in for the day only, passed the œsophagoscope, and took a biopsy specimen, which proved the presence of a squamous epithelioma of the œsophagus The patient steadily improved to the point that he could go out for walks on his farm and drive his car alone, and for six months he could swallow solids again About October, 1955, his condition began to deteriorate He was still getting injections of pregnyl but was very intolerant of them, they gave him a severe headache and made him go partially blind for a while For a time he refused point blank to have them, and it was only by telling him that he had a cancer that I could continue the treatment He died on Jan 10, 1956, having had about a year after he had been brought home to die

Discussion

Hormone therapy in inoperable or recurrent breast cancer is established, since Loeser (1940) initiated treatment with testosterone It was followed up by Adair and Herrmann (1946), among others, who have confirmed its temporary benefit Haddow et al (1944), Nathanson (1947), and Stoll and Ellis (1953) attempted to depress pituitary function by giving massive doses of œstrogen to inhibit ovarian secretion Huggins (1952), working on the assumption that the suprarenal glands may secrete a hormone which reactivates tumour growth, was the first to do bilateral adrenalectomy and oophorectomy, and Cade (1955), among others, reported favourable results of this combined operation in late carcinoma of the breast

The procedure outlined above has the merit of simplicity, but injections of *gonadotropic hormone* are not without danger The patient may become very intolerant of the injections, which probably have an inhibiting effect on the pituitary gland and cause it to atrophy, just as injections of insulin may cause atrophy of the islets of Langerhans

Though a five-year period of freedom from secondaries is not necessarily synonymous with recovery, the unusual feature of case 1 is that, despite *the clear and* successive emergence of secondaries throughout nearly two years, there seems to be no reason to doubt that the succeeding three and a half years' freedom from secondaries is due to the treatment she has had The growth was fairly advanced to begin with and had all the stigmata of a fatal carcinoma, yet the patient has survived and done well. Whether this degree of recovery is due to stilbœstrol, mixogen, or pregnyl, or a mixture of all three, at least it gives some sort of lead for further investigation

Although case 2 died, the remarkable if comparatively short-lived improvement suggests two things (1) cancers other than those of the breast and the prostate gland may be susceptible to hormone therapy, and (2) the effect of the pregnyl injection appeared to be equivalent to that of a surgical operation, for in both cases there appeared to be an equal degree of regression of the growth followed in 1 case by recurrence and death

Summary

Two cases are presented of cancer one of mammary carcinoma involving axillary lymph nodes, and one of constricting carcinoma of the œsophagus The first patient is alive and well five and a half years after operation despite recurrences The second patient improved temporarily after treatment with pregnyl but subsequently died

VAGITUS UTERINUS

CRYING IN UTERO

P M G RUSSELL
M B Lond, F R C S, F R C O G
OBSTETRIC AND GYNÆCOLOGICAL SURGEON,
ROYAL DEVON AND EXETER HOSPITAL

THE word "vagitus" is derived from the Latin *vagire*, to squall, and is used by many writers including Pliny, Virgil, Quintilian, and Ovid, nearly always alluding to the cry of the newborn The historical background has been well reviewed by Ryder (1943), who found 122 well authenticated cases up to 1943 He surmises that physicians in the Middle Ages were loth to report cases for fear of religious persecution One might add that any midwife associated with such events might even have been accused of witchcraft

Case-history

A primipara, in good health throughout pregnancy, was admitted at term to Victoria Hospital Sidmouth, at 1 P M on Sept 10, 1952 The membranes had ruptured but no pains had been felt Even after castor oil an enema and then oxytocin, progress was slow The os was fully dilated at 8 45 A M on Sept 13 when a breech presentation was discovered The second stage was very long apparently because the legs were extended

At 2 30 P M, under nitrous oxide, oxygen, and ether, a deep episiotomy was done and a hand passed into the uterus to bring down a leg During this manœuvre a baby s cry was heard quite clear and coming from the mother s abdomen Dr Gibbens whose case this was describes it as a clear remote cry very like a baby crying in the next room but close below our heads It was heard by all three doctors present There was no other baby in the labour ward The sister was out of the labour ward at the time and on her return a few few moments later she was told that she had missed the chance of hearing a baby cry in utero However at that moment the baby gave another cry clearly audible to all in the room, and I had time to put my ear on the mother s abdomen and confirm beyond any doubt that it was the unborn baby that was crying in utero

Both legs were brought down and the aftercoming head extracted with forceps somewhat more rapidly than is usual because it was felt that the baby might drown in its own liquor He weighed 7 lb 2 oz and was a little limp at birth but he cried well after the air-passages had been cleared

The first stage lasted about sixteen hours, the second six, and the third one The child is now 4 years old and thriving

Discussion

Authenticity —Probably no one who has heard the cry can doubt its reality To dismiss it as merely a cry during the act of birth is absurd since in many cases the patient was not even in labour, and in the present case, as in Jackson's (1943) the head was in the fundus uteri There is no need to invoke "a vibrating fold of mucous membrane" suggested by some authors quoted in the *British Medical Journal* (1912)

In the light of Barcroft's (1946) famous work on fœtal respiration the occurrence of vagitus is more easily understood and need not surprise us As Barclay, Franklin, and Prichard (1944), whose studies were based on fœtal lambs have put it "the first breath of life is the culmination of over a hundred days of intra-uterine rehearsal and preparation" It is perhaps surprising that premature respiration does not occur more often

Conditions —Kitzmiller and Mitchell (1942) say that three conditions should be fulfilled

(*a*) The membranes must have ruptured

(*b*) There must be some operative manipulation or asphyxia to stimulate the infant

(*c*) Air must enter the uterus

In Parviainen s case (1949) the cry was heard during the version of twins, and in Morton s (1924), during the application of forceps Crotty and Kuehnle (1948) had a somewhat similar episode with twins and prolapse of the cord when using caudal analgesia

In Fraser's case (1943) a whimper was heard while the mother was being washed, and made louder by "gentle external prodding" An air-bubble was demonstrable in utero by percussion and a splash Labour started thirty hours later, the child died after three hours In Field's (1943) case, air could be heard being sucked in through a Drew Smythe catheter during induction A cry was then heard, but labour did not start for fifty-four hours After delivery expression of the placenta was accompanied by expulsion of air from the vagina The baby cried at birth

Clinical Features —In the cases published, the child's cry is often strikingly loud, and usually heard by all present, not least the mother (Mitchell 1944) In one of the cases described by Brodhead (1914) it was even heard by another woman in an adjoining room In Allard s case (1912) the nurse referring to the unborn infant, remarked with true Gallic insight, "*On voit bien qu'il s ennuie, il pleure*" The mother asked her husband what it was that made such a noise!

It is remarkable that the child is often none the worse even though labour may not start for many hours as in Field s case One might suppose that the child would probably drown in utero but this rarely happens Stoeckel (1938) says that 8 out of 58 (14%) were stillborn Ryder's figure is 21 out of 112 (19%), which he attributes to over-hasty manœuvres to deliver the baby Ryder's view is probably correct, and in our case efforts to deliver the baby were undoubtedly unduly hurried, because we then knew less about the subject

Little has been recorded about the extent of aeration of the lungs even in fatal cases Presumably it is patchy, leaving a vital amount of lung tissue to expand in the ordinary way after birth, otherwise one would expect a higher mortality from drowning.

Summary

A case of vagitus uterinus is described and the literature reviewed. Birth trauma from over-hasty attempts to deliver the baby is a bigger danger than drowning in utero.

I am greatly indebted to Dr. Gerald Gibbens, of Sidmouth, for his collaboration and notes on the case.

Preliminary Communication

SENILE CONFUSION AND THE BLOOD-SUGAR LEVEL

In elderly diabetics with cerebral arteriosclerosis the biochemical and clinical findings do not always tally.[1] In 3 of the 5 cases recorded here, attacks clinically resembling those of hypoglycæmia were associated with a relatively high blood-sugar; and in 4 of these 5 cases mental deterioration was arrested or reversed when hyperglycæmia was deliberately permitted.

CASE-HISTORIES

Case 1.—A retired nurse, aged 89, had diabetes mellitus recognised in 1948. On Jan. 29, 1951, her pre-lunch blood sugar was 200 mg. per 100 ml.,[2] with glycosuria. Next day, because of a mild respiratory infection and mild mental confusion, her daily dose of 30 units of insulin (protamine zinc and soluble) was supplemented by 20 units of soluble with 100 g. glucose. On Feb. 1 confusion proceeded to coma, with bilateral extensor plantar responses. Despite glycosuria and a raised blood sugar (it proved to be 160 mg. per 100 ml.), clinical hypoglycæmia was diagnosed, and striking improvement followed administration of glucose (100 g. by Ryle's tube and intravenous infusion of glucose and physiological saline solution). Withdrawal of her insulin did not produce ketosis, and her condition—general and mental—improved so much that during the next few months she pottered round the ward, taking a great interest in the nursing. In October, 1951, she was again put on insulin (12 units protamine zinc) and her condition remained satisfactory; but her activities dwindled until she died in 1955 of bronchopneumonia following fracture of a femur. Necropsy showed generalised arteriosclerosis but no additional pancreatic or other lesion.

Case 2.—A widow of 70, who was very alert, was admitted with symptoms of diabetes mellitus and ulcers of her legs due to pemphigus vulgaris. Her blood sugar after breakfast was 641 mg. per 100 ml. She was given a diet low in carbohydrate, and increasing doses of insulin. Alarming torpor developed twice and on both occasions was relieved by oral glucose, though on the first the blood sugar had been 265 mg. per 100 ml. She died soon afterwards with aspiration pneumonia. Necropsy showed cerebral and other arteriosclerosis and a small flabby pancreas.

Case 3.—A housewife aged 74, who had been given insulin (20 units of soluble and protamine zinc daily) for four months for diabetes, was admitted after a behaviour change; she had twice tried to set fire to the house. She was uncooperative and confused, but her normal mental state returned at once when she was given intravenous and oral glucose, though the blood sugar before treatment had been 315 mg. per 100 ml. No more insulin was given and her general condition improved though the blood sugar remained around 500 mg. Nine months later she died from pulmonary oedema after infarction of the right cerebral hemisphere. Necropsy showed generalised arteriosclerosis and a decrease in pancreatic islet tissue.

Case 4.—A spinster aged 62 had had diabetes for four years treated by diet and soluble insulin, 60 units daily in divided doses. She was transferred to hospital from a welfare home with a gangrenous ulcer of her right leg, where the pulses were absent from the foot. The same diet and insulin dosage were continued. Three weeks later she had an episode of giddiness and incoherent babbling which was attributed to a minor cerebrovascular accident in the right hemisphere. For several weeks she was incontinent and miserable and did not speak. Her mid-morning blood sugar at this time was about 180 mg. per 100 ml. Insulin was withdrawn and carbohydrate restricted; her corresponding blood sugar increased to over 320 mg. Gradually she became more alert and continent, and it was found that she was supplementing her diet with sweets, which she insisted that she needed; she was persuaded to accept extra dietary starch instead. Nine months after admission she was so much better that operation for her cataract was deemed worth while. She continued to improve and was active till she was immobilised by a patch of gangrene which made amputation necessary.

Case 5.—A spinster of 62 had behaved oddly since a cerebrovascular accident four months earlier. She had been given insulin for a short period for mild diabetes. Her condition was static and she was admitted to hospital, making agitated gestures and unintelligible sounds. Preprandial blood sugars were below 200 mg. per 100 ml. Her carbohydrate intake was increased till the corresponding blood sugars were over 400 mg. Within a week she began to respond to encouragement and she was able increasingly to make herself understood. Finer movements returned to both hands. This very satisfactory progress has been maintained up to the time of writing.

DISCUSSION

In cases 1–3, disturbance of consciousness typical of hypoglycæmia and responding to glucose was seen at capillary blood sugar levels of 160, 265, and 315 mg. per 100 ml. It is unlikely that the blood-sugar was lower shortly before these determinations (e.g., in case 1 an extra 100 g. of glucose had been given at 8 A.M. on the day of her attack) or that glucose relieved cerebral oedema from some other cause. Transient cerebral anoxia is difficult to exclude absolutely, but there was no apparent cause for it. Fabrykant and Bruger[3] pointed out that the clinical symptoms recognised as the hypoglycæmic reaction are merely an expression of disturbed brain function which is common to many reactions including cerebral anoxia.[4] Focal cerebral disturbance associated with and following hypoglycæmia has been clearly described.[5] It has recently been emphasised that the surest confirmation of the hypoglycæmic nature of an attack lies in its response to glucose[1]; and, though Post[6] refers to relief of non-specific senile confusional states by the infusion of glucose, he says that the reason for it is not clear.

Himwich[7] attributes the infrequency of hypoglycæmic reaction in babies with subnormal blood-sugars to a lower local metabolic requirement than in adults, and, referring to this, Fabrykant and Bruger[3] suggest an opposite state of affairs in adults, where, with normal blood sugar values, the supply of sugar to the brain may be less than is needed. What may be more important in the former is the relatively high cerebral blood-flow early in life[8] which will ensure adequate glucose delivery despite the low concentration. This state of affairs contrasts strongly with that governed by the precarious cerebral circulation of the aged arteriosclerotic subject.[9] Himwich[10] elsewhere has shown that oxygen utilisation in the brain depends on an adequate supply of glucose, the mediation of insulin not being required in this situation.

[7] Himwich, H. E. *Amer. J. digest. Dis.* 1944, 11, 1.

These case histories suggest that in the elderly diabetic with arteriosclerosis, and consequently reduced blood-flow, cerebral metabolism may become adapted to a supply of glucose in higher concentration than normal, and may be disturbed (in some cases irremediably) by reduction of the blood-sugar to normal. It is as though glucose in supernormal concentration may permit a higher level of cerebral metabolism, albeit perilously, than the reduced cerebral blood flow (and therefore oxygen supply) can otherwise support. Thus, though hyperglycæmia may do harm in other parts of the body, the optimal blood-sugar level in the *brain* of the arteriosclerotic diabetic may be higher than normal, and this will often be an overriding therapeutic consideration. The potential danger of aiming at chemical normality[11] is nowhere greater.

Cumulative cerebral disorganisation can take place without definite episodes as a result of slight but repeated or long continued deficiency of glucose in the brain. The trend of events in cases 1, 3, and 4 suggests that in the elderly arteriosclerotic diabetic this may happen with a normal or even a high level of blood-sugar, and that such mental deterioration may be reversed by letting the blood sugar rise. In case 5 advantage was taken of the patient's mild diabetes to ensure a hyperglycæmic state which appeared to improve recovery from a cerebrovascular accident. Ketosis must of course be avoided.

We might expect hyperglycæmia to improve cerebral metabolism similarly in the non-diabetic patient with reduced cerebral blood flow, and we have ourselves obtained encouraging though temporary clinical improvement, substantiated by electro encephalographic record, with continuous intravenous infusion of glucose in non-diabetic cases of senile confusion. We delivered directly into the great veins, by 'Polythene' tubing, 3 or more litres, according to circulatory or renal fluid tolerance, of 10% glucose in the twenty four hours. 3 litres a day is more than Post recommends, but other workers[12] have found that this rate and concentration produce no significant dehydration.

This measure may help in cerebral disturbance associated with short lived hypoxic states of remediable circulatory or respiratory origin. Oral administration of equivalent amounts of carbohydrate to non-diabetic subjects with arteriopathic mental change has been less promising, probably because it has not produced sustained hyperglycæmia. When one wants to maintain a high blood sugar for longer than can reasonably be done by continuous glucose infusion, it would be rational to use glucagon, corticosterone, or even somatotrophic hormone; work on these lines is planned.

My thanks are due to Lord Amulree for his encouragement and help and for permission to publish the cases, and to the laboratory staff of University College Hospital, London, for the blood sugar estimations.

Reviews of Books

An Outline of Bacteriology and Immunity

RONALD HARE, M.D., professor of bacteriology in the University of London, and honorary consulting bacteriologist at St Thomas's Hospital. London: Longmans, Green. 1956. Pp. 418. 35s.

ONE difficulty about teaching bacteriology to medical students is that the wider implications of the subject are often lost by emphasis on the diagnostic methods. The precise identification of bacteria and viruses is extremely important, but easy familiarity with all the technical processes is beyond the scope of an undergraduate training in medicine. Nevertheless this aspect is precisely that on which students and teachers alike are inclined to concentrate—the student because his textbooks emphasise it, the teacher because it is his daily work. In fact, the important thing is that the student should gain a clear idea of how infection spreads and of how the human body can be helped to resist the invasion of disease-producing *microbes*.

Professor Hare has done a real service by writing a book for students that is neither too long nor too costly but gives its greatest emphasis to such important subjects as virus diseases, epidemiology, and immunity. The chapters on immunity offer a particularly clear and interesting presentation of a subject that students often find difficult; chapter 6, on the host-parasite relationship, is notable for its wide range and stimulating approach. The illustrations are well above average quality for books of this kind. Students who use Professor Hare's text will be well able to meet their examiners and will gain some idea of what attracted their teachers to bacteriology. Altogether the book may be warmly commended.

Lymphatics, Lymph and Lymphoid Tissue

2nd ed. **JOSEPH MENDEL YOFFEY**, M.D., F.R.C.S., professor of anatomy, University of Bristol; **FREDERICK COLIN COURTICE**, D.PHIL., D.SC., F.R.A.C.P., director, Kanematsu Memorial Institute of Pathology, Sydney Hospital, Sydney. London: Edward Arnold. 1956. Pp. 510. 60s.

THIS volume is the third in succession to C. K. Drinker and M. E. Field's *Lymphatics, Lymph and Tissue Fluid*. The new edition is based on wide reading and the authors' own experiments.

The use of isotopes has confirmed and slightly extended previous knowledge about electrolyte exchanges through capillary membranes. Radioactive colloids have provided clues to the passage of particles through the bronchial tree, and electrophoresis has given more detailed information of the proteins and lipoproteins in lymph. Experiments with the war gases have extended knowledge of altered capillary permeability. Many knotty problems are still with us—for example, the hypothetical pores in vascular and lymphatic endothelium through which particles are able to pass. Some will deplore the continued use of the phrase "tissue space" for intercellular substance. Credit should be given, but is not, to W. H. Gaskell (*Ludwig's Arbeiten*, 1876, 11, 43) for resolving the puzzle of the opening of lymphatic channels in *œdema* when hydrostatic pressure outside them is greater than within. Discussion of the state of affairs in local urticarial and angioneurotic œdema would be welcome.

The intractable problem of the function of lymphocytes is discussed very fully. Since the view now finds support that plasma cells rather than lymphocytes are a source of antibodies, the lymphocyte is again left without apparent function. The reasonable opinion is adopted here that lymphocytes are important not for what they do but for what they develop into. On morphological grounds and making use of quantitative data the conclusion is reached that lymphocytes are continuously supplied to marrow. Only thus is it possible to account for the numerical output of red and white blood corpuscles, for which inadequate numbers of primitive blast cells are found in marrow. Lymphocytes, micromyeloblasts, and pro erythroblasts are here regarded as morphologically *indistinguishable*. This unitarian view of the origin of blood cells will enliven many old controversies

The Physiology and Biochemistry of Lactation

S J Folley, d sc, ph d, f r s, head of the physiology department, National Institute for Research in Dairying, Shinfield, Reading, Berks Edinburgh Oliver & Boyd 1956 Pp 153 18s 6d

This book is substantially a translation of the original French edition which was based, with little alteration, on a series of lectures given by Dr Folley at the Collège de France in 1953 It is the first work in English devoted to the subject of lactation Dr Folley and his co-workers, by their chemical and metabolic studies, are responsible for much progress in this subject

The book deals first with factors in the normal development of the glands postnatally and goes on to consider the initiation of milk secretion Dr Folley contends that development and lactogenesis are a response to the action of more than one hormone and that the endocrine glands supply a complex and delicately balanced dynamic equilibrium which may centre round the anterior pituitary and also depend on central nervous activity Only in the presence of this equilibrium is the whole process of lactation possible This argument is developed in the section on initiation and inhibition of milk production There is good evidence in man and animals that oestrogen and progesterone act synergistically in these processes and that the end result—initiation or inhibition—is determined by the absolute and relative amounts of these substances released In chapter 3, dealing with the maintenance of lactation, or galactopoiesis, it is pointed out that until we know the mechanism of this we cannot know whether hypogalactia is due to failure of lactogenesis or of galactopoiesis Dr Folley next surveys the mechanism of suckling and milking and the neuro endocrine control of the myoepithelial cells, then in the last two chapters deals with the biosynthesis of the solid constituents of milk This last section brings out interesting species differences thus, non ruminants can easily utilise glucose for the synthesis of fats, whereas ruminants such as the sheep must start from acetate From this it follows that the importance to milk formation of hormones such as insulin varies from species to species

This is an important and useful book

Lesions of the Cervical Intervertebral Disc

R Glen Spurling, m d, professor of neurosurgery, University of Louisville, Kentucky Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1956 Pp 134 36s

Professor Spurling describes this monograph as an account of his personal philosophy and practice on the subject of cervical-disc lesions, but it also contains a very comprehensive account of the anatomy, pathology, and clinical features of protrusions in this region

The diagnosis and localisation of the lesion is fully considered and effectively illustrated There is a detailed description of the technique of cervical myelography, but the accompanying radiographs are far from convincing The indications for, and the results of, surgical treatment of cervical disc lesions are based on a personal series of 197 private cases, of which 61 were treated surgically The results of both conservative and operative treatment are analysed, and there is an excellent account of the surgical procedures

The book, which is attractively written and beautifully produced, is a worthy companion to Dr Spurling's earlier monograph on lumbar-disc lesions

Freud and His Time

Fritz Wittels, m d, *formerly instructor at the* New York Psychoanalytic Institute London Peter Owen 1956 Pp 451 42s

The publisher does not indicate on the title page or elsewhere that this book was first published twenty years ago, but the reader becomes aware that the world for which the author was writing is not the one we live in It is difficult to see any central theme in the book it begins with Goethe's influence on Freud, it ends with a chapter entitled Einstein and Freud which discusses masochism in Indian philosophy, sadism and masochism in civilisation, 'our hurt narcissism," and the rights of man As a commentary on the Freudian doctrine, the book is too discursive to command contemporary attention

Tredgold's Textbook of Mental Deficiency (9th ed London Baillière, Tindall, & Cox 1956 Pp 480 40s)—First written in 1908 by the late A F Tredgold, this became and has remained, the standard English work on the subject In the past half century Tredgold's views on the neuropathic diathesis and the major influence of heredity in mental defect have been accepted rather uncritically, and consequently little attention was paid until recently *to social and* environmental causes or to the distinction in children between mental defect and mental disorder Dr R F Tredgold and Dr *Kenneth Soddy* have now rewritten much of the book The classical clinical descriptions have been retained, but a new chapter on Disorders of Relationship Formation contains interesting case histories which show the distinction between psychosis and amentia in childhood The book, nevertheless is in a difficult transitional stage, the old and the new material being separated by a generation Some of the illustrations are rather dated, and the rather sketchy drawings of abnormal brain cells should be replaced by photomicrographs The chapter on pathology would benefit from the inclusion of more modern material The omission of the chapter on the law relating to mental deficiency, because of impending changes, may leave the reader with an impression that feeblemindedness is a definite entity irrespective of its legal definition The same applies to the lack of a chapter on mental testing and its problems We hope that for the tenth edition the rewriting of this important work will be completed

New Inventions

A NEW SUPPORT FOR THE BOYLE-DAVIS GAG

This support fulfils the requirements of simplicity and ease of adjustment It may be made in any small workshop from materials usually available It consists of a length of $^{3}/_{16}$-inch steel rod bent to the shape shown (fig 1), the legs are 50 cm long, and the top cross piece 5 cm long A small stud is welded on to the cross piece *and angled slightly* A leather strap, with the usual holes enlarged and multiplied if necessary, completes the support The ordinary buckle of the strap is used to accommodate the hooked end of the Boyle-Davis gag Stability is ensured if the legs of the support are pressed close to the patient's shoulders and directed slightly backwards (fig 2) The length of the support enables it to be used for both adults and children

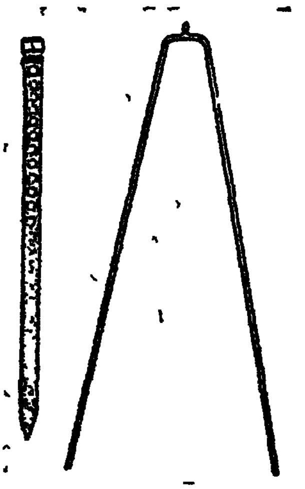

Fig 1

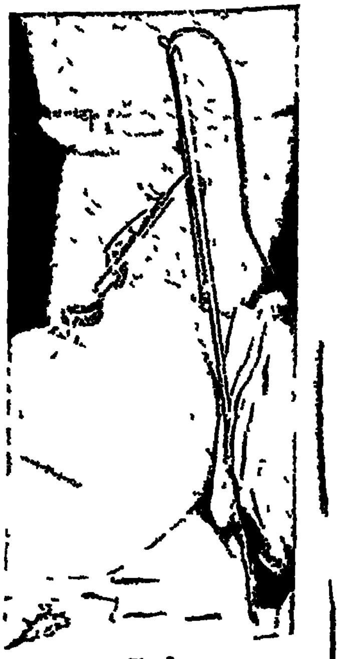

Fig 2

I wish to thank the Director-General of Medical Services, Royal Air Force, for permission to publish, and Warrant Officer W J Salzer, chief radiographer, for the photographs

THE LANCET

LONDON SATURDAY, JAN. 19, 1957

Coronary Disease, Serum-lipids, and Thyroid Hormones

THREE months ago there appeared an account of one of the most ambitious cooperative experiments ever devised[1] Organised by two committees of the United States National Advisory Heart Council, it was designed to examine the value of serum-lipid estimations in predicting clinical coronary-artery disease, and one type of lipid measured was the serum total-cholesterol It is well known that patients with clinical evidence of coronary-artery disease have, on the average, higher serum-levels of cholesterol than do unaffected persons of the same age and sex—a fact which has been demonstrated in many parts of the world, including Britain[2] In all such studies the clinical manifestations preceded the serum-cholesterol estimation, and it remained arguable that the raised serum-cholesterol might have been in some way a result of myocardial infarction rather than a cause of the underlying atherosclerosis Moreover, in these retrospective surveys, there has always been a large amount of overlap between the serum-cholesterol levels of the control and atherosclerotic groups, and this has led to many attempts to measure lipids by more refined methods Since serum total cholesterol showed a definite, but imperfect, correlation with atherosclerosis, it seemed a reasonable guess that some fraction might show a closer correlation Cholesterol is carried in serum in lipoprotein complexes, and these were fractionated by one of three methods Thus, RUSS et al[3] used Cohn fractionation, and (among many others) OLIVER and BOYD[4] used paper electrophoresis, in order to separate α and β lipoproteins In both instances serum-β-lipoprotein levels tended to be higher in those who had had a coronary infarct The difference between the two groups was possibly a little greater than when total cholesterol alone was estimated but even so there was a great deal of overlapping The third method of lipoprotein analysis was devised by GOFMAN and his colleagues[5] in the Donner Laboratory of the University of California The essential feature of their technique has been the use of the analytical ultracentrifuge, with control of the density of the medium by addition of salt solutions Under these conditions lipoproteins tend to float to the surface, according to their density and can thus be graded by their position in the tube To describe the results obtained by this technique the Donner group devised a new notation of Svedberg flotation (S_f) units Statistical analysis of a large series of patients with coronary disease and comparison with controls[6] showed that the S_f 12–20 group of lipoproteins was most closely associated with clinical manifestations Later work at the Donner Laboratory[7] led to technical modifications involving a change of scale to correct for the effects of concentration on flotation rates which had not been appreciated before Thus corrected, the "standard flotation-rates" are measured in S_f units From the revised values an "atherogenic index" (A.I.) was calculated in which the values for several flotation classes were combined in specified proportions to give a single figure

The combined committees of the National Advisory Heart Council (on which the Donner group was represented) set out to investigate these claims, and to determine whether serum-lipid levels were capable of predicting the onset of clinical coronary-artery disease It was an enormous undertaking four laboratories in different parts of the United States cooperated in some 15 000 serum-lipid analyses About two years were spent in securing agreement between the analytical results in the four laboratories Discrepancies in the values for serum total-cholesterol levels seem to have caused more trouble than the results of the more elaborate ultracentrifuge work. 4914 men aged 40–59 were then selected in different parts of the country, they had undergone a rigorous examination and been pronounced normal These men were followed for from one to two years, and during this time clinical evidence of disease of the coronary arteries developed in 82 of them The doctors who assessed their clinical state had no knowledge of the serum-lipid values In three of the laboratories it was agreed that the serum total-cholesterol level, on the whole gave better predictions of the likelihood of developing clinical manifestations of coronary-artery disease than either the S_f 12–20 or the S_f 20–100 lipoprotein classes but the Donner group were not able to accept this finding, and they state their reasons in an appendix to the main report It is a pity that this vast project, carefully planned and conscientiously executed, should end in a sort of stalemate over the interpretation of the results To the outside observer it seems evident that both serum-cholesterol and various figures derived from ultracentrifuge analysis have some value in assessing liability to overt coronary disease, but they do not predict the fate of an individual with any certainty Since the experts cannot decide which method is the most helpful in this respect it is reasonable to conclude that there is probably little to choose between them, save that S_f measurements require the very expensive ultracentrifuge and so are possible in only a few laboratories

There is no doubt that the serum-lipids are abnormal in some people who will shortly have a cardiac infarct or show other signs of coronary atherosclerosis At first sight, it seems an obvious precaution to try to lower the serum-lipid level in the hope of preventing or postponing these events, and various attempts have been made, using, for example, sitosterol, unsaturated fatty acids, or stilbœstrol **Oliver** and **Boyd**[8] have lately given evidence of the way in which certain hormones can influence cholesterol and lipid metabolism, and Professor **Gofman** and his colleagues, in an article on p 120, now amplify their suggestion[9] that thyroid extract might profitably be used in this way They gave it to 60 schizophrenic patients for a hundred and five weeks, starting with 3 grains and gradually increasing to 5 grains daily If they were using *U S P* dried thyroid, these doses would be equivalent to 6 and 10 grains daily of *B P* dried thyroid 39 patients completed this strenuous course (which seems to confirm the view that schizophrenics are unusually resistant to thyroid) There was an undoubted decrease in serum-cholesterol levels and in the level of all the S_f fractions measured and the atherogenic index fell considerably These changes persisted throughout the long experimental period, and there was no tendency to "escape," as had been observed by **Gofman** et al in an earlier experiment with a fixed dose of thyroid extract This supports their contention that, in experiments like this, it is necessary to make gradual increases in dose In the early stages the patient's own thyroid gland is adding substantially to the exogenous material, later the gland is inhibited, and any action is due entirely to the outside supply The biggest falls in total cholesterol and lipoprotein fractions and in the atherogenic index were observed in those patients who had the highest initial levels As the result of their inquiries, Professor **Gofman** and his associates suggest that thyroid extract is worth considering as a prophylatic agent against coronary heart-disease

An obvious disadvantage of thyroid extract is its capacity to raise the basal metabolic rate (B M R) as the serum-cholesterol level falls The work of the heart would thus be increased and patients whose coronary arteries were already narrowed might be much worse The observations of **Lerman** and **Pitt-Rivers**[10] pointed to a possible line of escape from this dilemma in 2 cases of myxœdema, treatment with the acetic-acid analogue of triiodothyronine (triac) produced a substantial fall in blood-cholesterol without detectable change in the B M R These results raised hopes that triac might control the blood-cholesterol level in euthyroid subjects without adding to the burden on the heart A tentative trial by **Trotter**[11] showed that it was sometimes feasible, by carefully grading the dose of triac, to lower the blood-cholesterol of patients with coronary disease without materially increasing the B M R On p 124 Dr **Oliver** and Dr **Boyd** describe further experiences with triac They confirmed that with suitable graded doses the blood-cholesterol could often be reduced (though it later tended to "escape") without increasing the B M R But in 2 of their atherosclerotic patients attacks of angina developed although the B M R did not increase This suggested to them that triac might increase cardiac metabolism, even without an increase in total metabolism as reflected by the B M R It seems, therefore, that triac is not likely to be any more or less useful than other forms of thyroid hormone for this purpose Other chemical variants of the thyroxine molecule may have more desirable properties, but the present evidence suggests that if this type of prophylaxis is to be contemplated at all, ordinary thyroid extract is probably better than any other preparation

The Donner Laboratory group have no doubt already set out to determine whether the administration of dried thyroid extract does actually prevent the clinical signs of coronary-artery disease, and many people will be wondering whether similar large trials should be started in this country The balance of evidence suggests that the results would be unlikely to justify the enormous effort involved There are two ways in which such a trial might be conducted

(1) A large number of healthy men of a susceptible age-group could be selected and half of them given thyroid extract The difficulty here would be mainly one of scale, for though the accumulated morbidity and mortality from coronary-artery disease is high, the annual attack-rate is relatively low It would be necessary, therefore, to observe an enormous population for a fairly short time, or a smaller population for a longer period In either case it would be hard to ensure that the thyroid extract was, in fact, being taken regularly

(2) Patients known to have coronary-artery disease could be given thyroid extract to see whether it would prevent further episodes of coronary insufficiency This plan would be easier, but it would call for very careful clinical observation, because thyroid extract may aggravate the symptoms of angina This type of experiment implies that thyroid extract has something of a curative as well as a prophylactic action in atherosclerosis

The effort needed to launch and sustain either type of trial on an adequate scale would be justified if there seemed a reasonable prospect of helpful results, but at present the picture is not encouraging In the first place, it is still far from certain that a raised level of either cholesterol or any other lipid in the serum is a direct cause of atherosclerosis or coronary infarction Certainly there is some connection, but in view of the relatively poor correlation in individuals between the biochemical and clinical events, as recorded by the two American committees, it may well turn out to be a second-order or indirect relationship Though it is probably a good thing to lower serum-lipid levels, there are several other ways of doing so (for example, changes in the diet) which would be safer than large doses of thyroid extract to a patient whose coronary arteries are already damaged Nevertheless, further news of research along these lines will be eagerly awaited

Reflux Œsophagitis

Normality is precariously balanced at the junction of stomach and œsophagus, if one thing goes wrong, other difficulties ensue, and achalasia of the cardia illustrates the point Surgical relief is often followed by œsophagitis, and in the experience of **Brewer** et al,[1] in New York, œsophagitis is commoner after operations which interfere with the junction, such as cardioplasty or œsophagogastrostomy Of 15 patients treated thus for achalasia, 11 ultimately had œsopha gitis, some with stricture as compared with 2 out of 13 treated by Heller's myotomy alone (follow-up was however shorter in the myotomy group) Reflux of gastric contents into the œsophagus after distortion or destruction of the cardia is thought to be the cause of failure, and yet SWEET,[2] who used in 21 patients a form of œsophagoplasty[3] similar to the cardioplasty performed at the New York Hospital found only 4 whose symptoms were not relieved in a follow-up period of three to twelve years, stricture developed in only 2 patients in this group, and 2 required gastric resection for hæmorrhage due to gastritis SWEET, however, recognises two forms of achalasia one in which an atrophic muscle layer is present in 75% of cases and which is suitable for the plastic operation, and another in which there is thickening due to hypertrophy of the circular muscle-fibres and which is curable by Heller's myotomy Already one of the causes of difficulty and confusion is apparent—namely, terminology—for what SWEET calls œsophagoplasty includes a longitudinal incision, sewn up again "circumferentially," or transversely, "the lower limit of which must be at or just distal to the cardia"[3], though it is not implied in the terminology, disturbance of the cardia must take place and may give rise to reflux WOLF et al[4] have indicated the further confusion that arises from the terms "peptic œsophagitis" and "peptic ulcer of the œsophagus" and, though they have tried to adhere to the classification derived from the work of ALLISON and of BARRETT, they have added yet another term—"marginal œsophagogastric ulceration" Meanwhile, MARCHAND has pointed out that there is nothing specific about the irritant which produces the symptoms of regurgitation dyspepsia, the reflux of gastric contents may contain irritants, in the form of acid, bile, products of partial digestion, and pepsin itself[5] In MARCHAND's view it is the persistence of reflux that leads to œsophagitis, "peptic" therefore seems an inappropriate prefix, and "reflux œsophagitis" is preferable since it is more inclusive

[1] Brewer McH S, Barnes, W A, Redo S F *Ann Surg* 1956 144 823

Another result of MARCHAND's work has been further to dispel the *idée fixe* that associates hiatus hernia with œsophagitis Though the two commonly occur together it is not always so, many changes can promote regurgitation and doubtless they act together in a complex way Rise in intra abdominal pressure is one, MARCHAND found that 182 of 250 pregnant women who were interviewed one week before delivery had had heartburn during pregnancy, though only 3 had had this symptom before All symptoms ceased after delivery, and in 20 of 78 primigravidæ heartburn was relieved during the final month, presumably by the descent of the fœtal head This is not to deny that hiatus hernia may be seen and can perhaps develop during pregnancy, though MARCHAND was unable to find a single case among the 14 patients with severe symptoms who agreed to X-ray examination with barium GORBACH and REID,[6] however, demonstrated a hernia radiologically in 31 out of 50 antenatal patients with heartburn, nausea, vomiting, or hæmatemesis

One fact does seem to be clear—namely, that œsophagitis, except in the extremely rare case,[7] is due to regurgitation Furthermore, surgical interference with the cardia can lead to reflux, and many other conditions may so alter the anatomy and physiology of the œsophagus and cardia as to create incontinence Less emphasis is now being placed on the diaphragmatic pinchcock described by ALLISON,[8] and more on the possibility of intrinsic sphincteric action Recent experiments by BRAASCH and ELLIS[9] point to the œsophagogastric junction itself as the important site in maintaining gastro-œsophageal continence, for cardioplasty, œsophagogastrectomy, or œsophagocardio-myotomy in dogs was followed by œsophagitis just as often when the new œsophagogastric junction was placed in the thorax as when it was in the abdomen when, however, the junction was maintained intact but a short length of abdominal œsophagus produced, no œsophagitis developed within the segment now below the diaphragm and no longer safeguarded by its supposed pinchcock Indeed LYONS et al[10] go so far as to consider that the presence of an internal sphincter is established, though they do not think that it alone is responsible for continence Nevertheless, in man the diaphragm may play some part in the maintenance of the œsophagogastric angle and thus affect continence in a rather less direct way than is implied by the pinchcock hypothesis

Since the œsophagogastric junction must inevitably be disturbed by a resection or any plastic operation in that area, devices must be found to protect the œsophagus from reflux MERENDINO and DILLARD[11] used a method of jejunal interposition based on animal experiments which showed that the interposed section of jejunum suffered in no way from contact with gastric contents, and if it was sufficiently long it prevented reflux into the œsophagus above it The results of this operation were encouraging, though follow-up has so far been short Longer observations are those of WANGENSTEEN[12] who seven years ago first exploited the idea of partial gastrectomy for œsophageal stricture Though it was originally based on the association of œsophageal stricture with gastric or duodenal ulcer,[13] the operation has since been used by WANGENSTEEN in the absence of gastric or duodenal disorders, on the ground that rapid emptying of the stomach from below will minimise regurgitation of gastric contents, which are themselves less irritant as a result of the resection In 18 patients observed for periods of up to sixteen years after operation, the dysphagia completely disappeared or substantially improved In 7 the stricture was associated with hiatus hernia, in 4 there was no other abnormality, and in the other 7 a duodenal or gastric ulcer was present In all but 3, subtotal gastrectomy was performed the œsophageal lumen subsequently increased and this change persisted In another patient who failed to respond the stricture was due not to reflux but to swallowing a corrosive

The Search for Tuberculosis

In those countries with the most complex social and industrial structures, the emphasis in case-finding in pulmonary tuberculosis gradually shifted from mere routine follow-up of contacts to mass X-ray surveys, but lately there has been a swing back to detailed and painstaking Mantoux-testing whenever possible On the whole, mass X-ray surveys are of limited value, and they are certainly rather expensive in man-power and money But many such surveys have been made of highly selected groups, such as hospital patients, old people, prison populations, people in social class v, and "Skid Row" victims, among whom a high prevalence of tuberculosis might be expected Other groups may have a high susceptibility to the disease—school-leavers, students, and nurses And there are also the food-handlers, child-minders, and school-teachers who may act as reservoirs of infection Surveys of all these groups, however, can form an impression only of the amount of disease discoverable at the time of the survey and they can give but little account of the social and economic background of the individuals and their families It was left to **Cochrane** and his colleagues,[1] during a study of the prevalence of a number of common diseases in an industrial community in the Rhondda, to try to assess the attack-rate for pulmonary tuberculosis The success of their initial survey and the subsequent follow-up was attributed in part to certain local conditions, such as the closely defined population and the ever-present threat of pneumoconiosis among the men, and it was thought that it might be more difficult to do the same thing with equal success in other areas and among other populations **Cochrane**, **Miall**, and **Clarke**[2] now report the results of a chest X-ray survey in an agricultural community in the Vale of Glamorgan, which was chosen for three reasons country-dwellers were reputed to be healthy, the results would provide a norm for future comparisons, and it was near the Rhondda Fach The population was defined as those aged 5 or over in July, 1955 An X-ray examination of the chest was made in 2688 (94%) out of 2880 males and 2697 (95%) out of 2841 females These striking figures for the Vale are a little better than those for the second Rhondda Fach survey and are apparently the best recorded anywhere for a voluntary chest X-ray survey The over-all prevalence of tuberculosis was low, and when the figures were compared with the results of the Rhondda survey the difference was much greater for females (0 7 per 1000 as against 6 7 per 1000) than for males (1 5 and 4 6 per 1000) But it is clear that the smaller difference for males is explained by the similar prevalence among elderly men in the two areas The yield of previously unknown infectious cases was 0 9 per 1000 in the Vale, compared with 2 2 per 1000 in the Rhondda

Springett[3] has shown that the radiological attack-rate for tuberculosis of reinfection type is similar in the two sexes and largely confined to young adults A difference in attack rate between the two areas over a period of time would account for the difference in the prevalence of clinically significant tuberculosis at the younger ages, but it cannot explain the similar prevalence among the older men in the two areas **Cochrane** et al[2] incline to the view that population densities are important in the Rhondda there are 4 7 persons per acre, but in the Vale the figure is 0 5 Overcrowding is much less important because the indices are nearly identical (Rhondda 0 7, Vale approximately 0 7) There is also evidence, from a study of a selected cohort, that in fact the attack rate is falling in the Vale

Whole-community surveys of this kind are very valuable, and there is useful guidance to be had from examining the methods which gave such highly successful results **Cochrane** et al did not attempt a "fast tempo" survey, such as the survey carried out in Bootle last winter and described on p 153 Their first step was to take an accurate census, and this in itself was probably the best propaganda weapon, then they visited at home those who did not come of their own accord, and finally the team never aimed to do anything beyond their capability We hope that the lessons learnt in the Rhondda and the Vale will be applied in other parts of the world, especially in those black areas where tuberculosis is still a very common disease

Annotations

SOIL, FOOD, AND HEALTH

Before the war Boyd Orr[1] showed that, even in our own prosperous country, millions of people were not getting enough of certain foods Their diet was in many respects deficient in quantity, and this remains true for a large proportion of mankind But nutrition may also be unsound when food-supplies are abundant, and attention is now being paid (1) to damage done by taking certain foods in excess of need, and (2) to the possibility that modern methods of producing and processing foods may damage their quality In agriculture the use of fertilisers to produce larger crops might conceivably alter the biological value of these crops for man and animals, and, fearing that the health of the soil, on which all crops depend, may be impaired by chemical treatment, some people are now demanding an agricultural counter-revolution—urging a return to the traditional methods by which the soil was kept in good heart almost wholly by the use of animal and vegetable waste, applied as manure and compost Without committing themselves so far as this, many think it important that we should at least know what we are doing, and that the advantages and disadvantages of "natural" and "artificial" soil treatment, and the nutritional value of their products, should be compared by all the scientific means at our disposal, and in asking for support of such a comparison on its experimental farms at Haughley the Soil Association has readily obtained from 400 members of the medical and dental profession their signature to the declaration published on p 152

To most agriculturists the suggestion that farmers should again do without fertilisers seems unrealistic They admit, of course, that, in some parts of the world the land has been kept fertile for hundreds and even thousands of years by systematically returning to it all crop residues, dung, and domestic waste, and by resting it periodically under grass But this can happen, they say, only where production is not too intensive, where the

---

1 Food, Health, and Income London 1936

population is relatively sparse and evenly distributed, and where the soil is not naturally deficient in some essential mineral The changes in our social and sanitary habits, and the very great increase in population throughout the world, have inevitably changed the picture, if only because much of the manurial residue which used to find its way back to the land is now carried as sewage to the sea No amount of composting can now fully restore to farms the products which move out of them in the form of crops and livestock consumed at a distance , nor can the use of natural organic manures alone supply the trace elements which are deficient in the soils of considerable areas of the world's surface, such as parts of agricultural Australia (In the United States it is estimated that if all the readily available garbage and organic wastes were made into compost it would probably not provide more than 5–10% of the elements needed to keep the soil in a satisfactory state of production) As to the biological value of the product, it is agreed that any manurial system which alters the proportion of the leaf, stem, and flowering parts of a plant will affect the ratios of the individual proteins, and perhaps the concentration of free amino acids and non-protein-bound amino-acids , but we are told that no evidence of imbalance of amino acids, or adverse effect on proteins, attributable to the use of fertilisers, has yet been detected As regards the vitamin content of crops, the changes measured are said to be relatively small, but may be beneficial rather than otherwise for example, there is reason to think that, when the nitrogen content of wheat is raised, its content of vitamin B_1 will rise too Possible changes of this kind in the chemical constitution of particular plants are, of course, different from the change in the constitution of an animal's diet that may take place when pasture is improved Some farmers and veterinarians think that certain of the so called metabolic diseases of cattle (e g , acetonæmia, lactation tetany, and bloat) and enterotoxæmia in sheep, are on the increase, and that this is a result of growing more grass with the aid of fertilisers , and few would deny the possibility that excess of nitrogenous material, and deficiency of roughage, could be harmful Though they do not think that this risk should deter farmers from trying to get a maximum yield from their land, or from continuing the grassland improvement demanded by present economic conditions, agricultural authorities agree that the effect of such improvement must ultimately be judged by the condition of the animals for which it is done Their emphasis on production does not necessarily mean that the need for complementary investigation is ignored or neglected

The same is true of research on soil and on soil plant-animal relationships, on which work is being done in many countries ; and it would be wrong to suppose that the Soil Association is the only body interested in the "integrity and biological quality" of nutrient materials The association's objection to what is being done under official auspices is that the purpose of such investigations is mainly technological (the utilisation of what is known) rather than ecological (the exploration of relationships that are still unknown)—that they seek know-how rather than fundamental knowledge

> " Official experimental work, which is itself based on science fragmented into subjects and sub subjects though nowadays better coördinated than formerly, usually begins by fragmenting the material or problem it is investigating in order to examine weigh and measure components At a later stage equipped with the knowledge it has gained it selects and reassembles components, discarding some and introducing new ones until some formula is achieved which can be tested against other formulæ or material again by quantitative measurement
>
> The result as it finally emerges as a fertilizer prescription seeds mixture or animal ration or perhaps some chemical spray or additive may appear to work it may offer a short term cash profit to farmers But the procedure can reveal little about living Nature which is ill-adapted to survive such dissection Indeed, it can be said to substitute the technologists' 'know how for that of Nature, with the not infrequent outcome that factors ignored or brushed aside as being of only academic interest later give rise to fresh problems It may, by artifice, achieve synthesis , but it neither studies nor fosters *symbiosis*, that 'living together' process which is the key to relationships between soil, plants, animals and humans "[2]

Looking at agriculture in this way, the association argues that the conventional experiments with small plots of land are insufficient , they can never be more than detached fragments , and comparisons of different methods cannot be justified unless they are made on a farming scale The Haughley experiment, which started in 1940 and was taken over by the association in 1948, is described as " the only farm-scale experiment devoted to the scientific study of ecological aspects of farming —the relationships that develop between soil, plant and animal under controlled and observed conditions " The association, which might more easily have confined itself to spreading its gospel, deserves praise for devoting so much of its resources to an attempt to collect valid evidence Sir Cecil Oakes, as chairman of Haughley Research Farms speaks of a change not only in other people's opinion of the venture but " also, imperceptibly, in our own outlook , we are determined to conduct the research on such sound farming lines, with the best scientific advice obtainable, that any results which we can offer to the world will be acceptable as the products of true research "[2]

Therein lies the strength of the appeal now made for financial support for the Haughley experiment Its weakness lies in the difficulty of the investigation To the agricultural expert it may seem that the kind of measurements made are not going to yield satisfying evidence Can the previous treatment of the land be " largely written off," as is suggested ? Can the comparison between the two dairy-herds, as selected and reared, be really valid ? Some hold not only that this particular experiment, even if extended, can never produce the evidence needed, but also that to prove or disprove, by experiment, the thesis of the Organic Movement is virtually impossible

> To get the required results (writes one critic) " several generations of men, women and children living under comparable environmental conditions, would have to be fed on food derived from organic farming or mixed farming , and the farms would have to start from a common virgin or organic ' basis, with similar soil types and water tables."

To the medical observer it may seem either that the present experiment, though imperfect, is worth backing and perhaps improving , or that the agricultural research authorities would be well advised to design something better on the same lines Or he may think that the science of nutrition, and its many institutions, are now so advanced as not to need the stimulus of pressure from outside enthusiasts But at least he will agree that the subject deserves thought and that, in our present concern with the quantity of foodstuffs eaten, the possibility of their changing in quality should not be forgotten

TRIBUTE TO A PSYCHIATRIST

PSYCHIATRY, like other branches of social science offers many examples of personalities who are said to have " lived before their time " The reason usually given for the failure of ideas and reforms to survive their originators is that the public was not yet ready for them The outstanding work of Conolly and Tuke, for example, was recognised by contemporaries but failed to take firm root , it became instead the subject of repeated rediscovery Indeed, respect for the mentally sick, which was the keynote of their teaching, was until quite recently little more than an ideal and a slogan One of the main obstacles to the public understanding of psychiatry has been the mental hospital itself, for, though it occupied the centre of the field, it was geographically and spiritually isolated from the community it aimed to serve Reform within the hospitals was certainly needed, but it was not at first recognised that this largely depended on the development of external services It was necessary to show the public what psychiatry had to offer Only in this way could early treatment be secured, the need for admission to hospital prevented, and overcrowding reduced

---

[2] The Haughley Experiment *Journal of the Soil Association* October 1956

It may truly be said of Dr T P Rees that by his work outside Warlingham Park Hospital he made internal reforms possible in fact by teaching the public he created his own time The future of psychiatry depends on prevention, and mental health, like any other social reform, needs promotion, which can be achieved only by contact with society Dr Rees's contributions to mental hospital management are internationally accepted His concepts of the therapeutic community, respect for the individual patient, and the need for team-work among the staff have set the standard for British mental hospitals But it is significant that recognition of his work has come not only from within the medical profession but from the people of Croydon In conferring on Dr Rees the honorary freedom of their borough its citizens have shown their appreciation of the man and also their understanding of the worth of the community psychiatry he has practised

THE PLIGHT OF HOSPITAL PHARMACY

New salary scales have lately been announced[1] for hospital pharmacists, but, so far from attracting recruits to sustain a service on the point of collapse, they are likely to discourage newcomers still further because they compare so unfavourably with salaries in other branches of pharmacy and in the technical colleges and universities, and with those of other hospital staff, especially biochemists, physicists, and supplies officers The seriousness of the situation is illustrated by what has just happened in the Portsmouth hospitals,[2] where it has proved impossible to fill two vacancies in an establishment of nine pharmacists Advertisements produced no replies, and the group secretary sees worse to come because he expects that the hospitals will lose the staff they already have to new pharmaceutical factories in the district He made it plain that pressure on the overburdened staff was resulting in serious dangers

For several years hospitals have been losing many of their best pharmacists to retail and manufacturing pharmacy The new Burnham scale salaries for teachers in the schools of pharmacy are now likely to cause a further drift of better-qualified pharmacists away from the hospitals An assistant lecturer's pay is now considerably better than that of a pharmacist in the basic grade and roughly equivalent to that of a senior pharmacist, and a lecturer's salary is better than that of the highest grade of non teaching hospital pharmacist The salary of a senior lecturer is now approximately the same as that of the chief pharmacist of the largest teaching hospitals, and that of the head of department of one of the colleges of advanced technology is much above anything that the most fortunate teaching hospital pharmacist can expect from all sources even after many years' service Yet the qualifications, the type of knowledge, and the ability required of the chief pharmacist of a large non-teaching hospital, and the responsibility he shoulders, are comparable to those of a senior lecturer, and the same can be said of the chief pharmacist of a teaching hospital when compared with the head of department in a college

There has long been difficulty in filling posts in the basic grade of pharmacists, and this has extended in the past few years to senior staff and to chief pharmacists, even to those in the teaching hospitals Not long ago the chief pharmacist of one of the big London teaching hospitals resigned to join a pharmaceutical firm In addition to his higher pharmaceutical qualification, he had an honours degree in physiology with biochemistry as a major subject, and he could have earned a much higher salary as a biochemist In fact, any honours graduate pharmacist who has taken chemistry and pharmacology as finals subjects would do well to enter the hospital service as a biochemist rather than a pharmacist Several have already done so and some colleges are now advising their graduates of this possibility

Successive Ministers of Health have expressed their concern at the state of hospital pharmacy and their anxiety to see pharmacists of the right calibre as chief pharmacists, but they have done little or nothing to attract staff of the right type The increases of the past few years have barely met the rise in the cost of living and have not kept pace with increases in comparable professions The Whitley Council negotiations seem unable to resolve the problem The staff side, in putting forward a reasoned and moderate claim, pointed out that the last increase had not attracted new recruits into the service, and that there was a 27% deficiency of establishment in a representative sample of 187 hospitals In spite of convincing figures comparing pharmacists' pay with other rates in the N H S, all that was conceded was roughly a cost of-living increase Such experiences will convince many people that the Whitley Council is not used by the Ministry of Health as a negotiating machine and that it has become a method of dictating what salaries shall be.

The Whitley Councils have been criticised for the rigidity which bars hospital authorities from making special scales for posts of unusual responsibility—and this objection applies particularly in hospital pharmacy For example, to assess the chief pharmacist's *salary, hospitals are allowed from 1 to 40* points, but many hospitals, by this method of scoring, can raise double this number of points and yet their pharmacist's salary is the same as if they had only 40 Moreover, many pharmacists have been doing the work of group pharmacist since 1948 without extra remuneration, and a group duties allowance has not yet been made Elsewhere in the hospital service, biochemists and physicists already have a "special grade" of £1900 per annum above the normal "top grade," and hospital authorities have power to make higher scales in exceptional circumstances Consultants have merit awards, the new Burnham scales allow for special responsibility allowances for teachers in schools of pharmacy, whereby a graduate can command a much higher salary than a non graduate, and in the hospital service a catering officer with a dietitian's certificate gets an extra £40 a year Yet the request for a rise in the pharmacists' higher qualification allowance from £25 to £50 was refused in the recent claim It is not surprising that few graduate pharmacists enter the hospital service

The pharmaceutical work of the hospitals is at present being maintained by a dwindling nucleus of established staff, some of whom are too old to embark on another career, by those who want a few years' hospital experience before passing to other branches of pharmacy, and by locums, many of whom are temporary visitors from the Commonwealth, and some of whom have little hospital experience, yet are often employed for months on end at salaries greater than those of established pharmacists who have given the hospitals many years of valuable service. The cumulative damage of the past ten years' losses is becoming increasingly obvious. Patients and nurses are having to wait longer for drugs, mistakes are commoner than ever before, and there is a general attitude of discontent in the hospital pharmaceutical service. Unless prompt action is taken to raise hospital pharmacy to an attractive career, as recommended by the Linstead report, the service will soon collapse. As we said[3] of the radiographers' situation, the new salary scales will do little to put things right.

[2] *Portsmouth Evening News* Jan 4, 1957

PLEURAL BIOPSY

THE unusual causes of "pleurisy with effusion" are fairly easily diagnosed at an early stage,[4] but the common causes are often hard to differentiate rapidly. It has become the custom to consider the condition tuberculous in the young and to suspect malignant disease in older patients, and to wait until the results of repeated tests (which may never become positive) or the clinical course decide the issue. With the changing habits of disease, however, tuberculosis is now appearing more often in older patients[5] and malignant disease more often in the young. An early diagnosis is thus much more important and, as a result, standard methods of investigation are becoming more accurate. In the effusions eventually believed to be tuberculous, it has been shown[6] that the number of positive results is greatly increased by using much larger amounts of the pleural fluid and clot for the bacteriological tests. The methods of searching for malignant cells have also been improved, both by the examination of smears[7] and by histological section of the sediment though sometimes the cells are too disrupted for either method. But even so these methods may be time consuming and still give no definite results in a fair proportion of cases.

Before the days of chemotherapy for tuberculosis it was too risky to undertake even minor chest operations in patients who might have active tuberculosis, but it is now possible to remove a biopsy specimen by thoracotomy and examine the tissue histologically. At first,[8] [9] this operation required a thoracic surgeon in an operating-theatre, positive pressure anæsthesia, and the removal of fluid and air by catheter before the wound was closed, but it enabled the pleura[10] to be observed and a piece of tissue about 1 5 × 3 cm to be removed for examination.[11] Now, Breckler and his colleagues[12] have modified the procedure to remove only a small portion of pleura by special forceps. They point out that though the pleura may be thin and glistening, it may still be involved by granulomatous disease. Even if pneumothorax does result, suction by catheter can be started immediately and no harm is done. An even simpler technique is described by Heller et al[13] (and also used independently by De Francis et al[14] and Katz et al[15]), consisting of needle biopsy, as for biopsy of the liver and kidney. The advantages are that it can easily be repeated in another site if the first result is equivocal, and the risk to the patient is negligible.

These new methods have enabled a much quicker diagnosis to be made in many cases of pleurisy with effusion, not only between tuberculosis and malignancy but also in several of the more unusual causes. At the same time, no specific cause could be found in some cases: some showed non specific fibrosis of the pleura after sulphonamide-treated pneumonia, trauma, or lung infarct, and a few other conditions were not diagnosed at all but were kept under observation until the condition cleared up. In this last group it was very useful not to have to embark on a full course of antituberculous treatment.

In another way these observations are helping towards an understanding of tuberculous pleurisy. In most of the recorded series the finding of tuberculosis by biopsy was sometimes as definite when culture from the pleural fluid was negative as when it was positive and negative biopsies were never associated with positive cultures. The implication is that there is widespread tuberculous granulation tissue throughout the pleural cavity when the tubercle bacillus is the cause of the pleurisy and that it is not a question of collateral effusion or hypersensitivity. This point requires much more evidence to be in any way final although Stead and his colleagues,[16] who examined tissue removed at decortication from 24 patients with pleural effusion suspected of being tuberculous, found evidence of tuberculosis in only 15—thus emphasising the frequency of non-tuberculous effusions.

THE REFUGEES

WITH more arrivals in prospect, we may soon have exhausted the £390 put at our disposal for the relief of Hungarian doctors in this country. We should be very glad to have further contributions—as many as possible, however small—from readers.

Of forty odd Hungarian doctors that have so far arrived in this country, perhaps a third have friends or relations here who are housing them and doing what they can. Of the others the majority are temporarily accommodated in medical households, but two at least have rented rooms and are living on their own. Some six or eight have gained hospital appointments.

Possibly half these doctors have decided to emigrate, if they can, usually because they believe that overseas the openings are greater or they will establish themselves more quickly. Except for the lucky few who know English, each one needs urgently to learn our language, for until he does so he cannot resume his professional work.

The *Lancet* fund is being used for three main purposes: first, to help clothe the doctors and their families, some of whom arrived with only the clothes they wore; secondly, to provide for small expenses and to help meet other immediate needs, including the need for prompt tuition in English (through the purchase of special long playing gramophone records which may be had on loan from this office[17]), and thirdly to help maintain the two who are living for the time being in lodgings supported otherwise only by grants from the National Assistance Fund.

These doctors want above all to work and pay their own way, and in their present dispiriting period of dependence and uncertainty they deserve well of their more secure colleagues. Contributions intended for them may be sent to the Editor of *The Lancet* and marked Hungarian Doctors' Fund.

DR JOHN MCGRATH, consulting State pathologist for Eire and professor of pathology and bacteriology at University College, Dublin, died on Jan 11.

UNMARRIED PARENTHOOD*

ECOLOGICAL ASPECTS

CYRIL GREENLAND

SENIOR PSYCHIATRIC SOCIAL WORKER,
CRICHTON ROYAL, DUMFRIES

OF every 1000 children born in 1954 in Scotland 45 were illegitimate. This was a considerable improvement over the previous ten years, but an illegitimacy-rate of even 4·5% remains a cold statistical fact tending to conceal rather than to reveal the wide variety of situations in which a baby is born to parents not married to each other.

The illegitimate child starts life with considerable handicaps. His chances of death are 70% higher than those of the legitimate child. The infant mortality rate among legitimate children in 1953 was 30 per 1000 live births compared with 51 per 1000 illegitimate children. This means that 212 of the 4177 children born in Scotland to unmarried mothers did not live a year. Many of the survivors face a host of new hazards—social, emotional, medical, moral, and legal.

Faced with these problems those who care about the suffering of little children have a healthy desire to understand and eventually to overcome the grave disadvantage with which the illegitimate child starts life. This is one of the principal aims of the Scottish Council for the Unmarried Mother and her Child.

My present aim is to describe briefly some of the known characteristics of unmarried parenthood and the environmental setting in which illegitimacy may be regarded as a major problem—the geographical factors in illegitimacy, the relative influences of religion, and the ages and civil status of unmarried parents.

As regards the wider aspects of illegitimacy, which are beyond my present scope, I suggest that further consideration might profitably be given to the prevailing cultural and economic factors. For example, Dr. J. R. Rees, director of the World Federation for Mental Health, who visited Latin America in 1954, reported that 75% of the children of Peru were illegitimate (Rees 1954). This he attributed not, as one might expect, to some widespread and deep-seated Peruvian neurosis but, among other circumstances, to the high cost of getting married in that country.

TABLE I—BIRTH OF FIRST CHILD WITH DURATION OF MARRIAGE 8 MONTHS OR LESS

(From Table 12, Annual Report of the Registrar General for Scotland 1953)

Age (yr.)	Total	Under 8 mos.
16–19	2688	1750 (65·1%)
20–24	13,937	3404 (24·4%)
25–29	9399	967 (10·1%)
30–34	3921	316 (8·06%)
35–39	1329	133 (10·0%)
40–44	314	42 (12·3%)
45–49	23	
All ages	31,611	6612 (20·9%)

Distribution of Illegitimacy

It is particularly important to consider the social and moral climate in which illegitimacy prevails. In Scotland (table I) 6612 (20·9%)—roughly 1 in every 5—of the women giving birth to a first baby in 1953 had been married for less than nine months. In the 16–19 age group 65%, and of the women aged 20–24 years 24%, were pregnant when they married.

Table II shows that a similar situation prevailed in England and Wales.

These figures only hint at the real incidence of premarital sexual intercourse, and suggest that premarital chastity is the exception rather than the rule at present.

Glass and Grebenik (1955) claim that conception before marriage is associated with high fertility. In their group of most fertile women 25–30% gave birth to a live child before they had been married 8½ months. "In such circumstances," these workers state, "prenuptial conception cannot be regarded as abnormal."

It is therefore no longer possible to regard the unmarried mother as necessarily less stable or less moral than her married sister when the only difference may be her very much higher fertility.

Geographical Factors

In 1890 the incidence of illegitimacy in Scotland was calculated to be 7·5% of all births (Lamond 1892). This incidence was twice as high in southern rural and in the north-eastern rural counties. The lowest incidence of illegitimacy was in the densely populated counties of Lanark and Renfrew.

Sixty-three years later almost exactly the same situation prevailed (fig. 1). In 1953, over the whole of Scotland, the rate of illegitimacy was 4·6% of live births. Illegitimacy was highest in the counties of Wigtown in the south-west and of Caithness and Banff in the north-east. The lowest incidence is still to be found in and around Lanark, Renfrew, and, especially, Selkirk.

TABLE II—BIRTH OF FIRST CHILD WITH DURATION OF MARRIAGE 8 MONTHS OR LESS

(From Table LL, The Registrar General's Statistical Review of England and Wales for the Year 1953)

Age (yr.)	Total	Under 8 mos.
16–19	22,137	15,372 (69·4%)
20–24	111,614	25,515 (22·9%)
25–29	74,917	6050 (8·1%)
30–34	28,825	1921 (6·6%)
35–39	8643	550 (6·3%)
40–44	1980	125 (6·2%)
45–49	122	9 (7·3%)
All ages	251,187	49,504 (19·7%)

In an attempt to explain this curious fact I studied the population structure over the whole of Britain and Ireland. I assumed that the risk of illegitimacy was greater in some counties than in others because of an imbalance of the sexes. If, for example, a population consisted of 100 single women of marriageable age and only 50 men, the risk of illegitimacy would be greater than in a county where the position was reversed.

Fig. 2 shows the counties with a surplus of men and those with a surplus of women of reproductive age. Contrary to popular belief, there are few areas where nubile women outnumber single men. In Scotland the counties of Aberdeen and Angus in the north, and Peebles, Lanark, and Renfrew in the south-west, have an apparent excess of unmarried women. Peeblesshire, which has the highest surplus of single women, has a fairly low illegitimacy rate. Aberdeen and Angus, on the other hand, have a surplus of unmarried women as well as a rate of illegitimacy above the average.

The methods used in making these estimates are relatively crude. But in spite of this the evidence is sufficient to indicate that there is no absolute relationship between a surplus of unmarried women and a high illegitimacy-rate. It still remains a mystery why the illegitimacy rate in Wigtownshire (15%) is three times as high as the average for Scotland (4·6%) when single men aged 15–44 (3783) outnumber single women (2566) by roughly 3 to 2 (table III).

---

* An address given in May, 1956, at the annual conference, in Glasgow, of the Scottish Council for the Unmarried Mother and her Child.

Religious Denomination

The study of the geographical distribution of illegitimacy in Britain also permitted a comparison to be made between Eire, predominantly Roman Catholic, and northern Ireland, predominantly Protestant The Roman Catholics comprise well over 90% of the population of Eire, and about 34% of the population of Northern Ireland

TABLE III—AGE DISTRIBUTION OF SINGLE MEN AND WOMEN IN WIGTOWNSHIRE

(From Table 11 of the 1951 Census Report)

Age (yr)	Single men	Single women
15–19	1415	1064
20–24	1110	568
25–29	540	326
30–34	289	221
35–39	222	189
40–44	207	198
	3783	2566
Widow/widower and divorced	56	116
Total unmarried	3839	2682

TABLE IV—POPULATION, BIRTH RATE, AND PERCENTAGE OF ILLEGITIMATE BIRTHS IN EIRE AND NORTHERN IRELAND

—	Population*	Birth rate†	Percentage of illegitimate births‡
Eire	2,960,593	21·1	2·5
Northern Ireland	1,370,709	20·9	2·8

* 1951 census
† Per 1000 population 1953
‡ Per cent of live births 1953

Illegitimate births represent 2·5% of live births in Eire and 2·8% in Northern Ireland (table IV) This appears to indicate that factors other than religion are responsible for the low incidence of illegitimacy in these countries

A comparison of the relevant data for other mainly Catholic and mainly Protestant countries reveals an incidence of illegitimacy of 3·4% in Italy and 5·2% in Spain In the Netherlands the percentage was 1·5%, in Norway 4·1%, and in England and Wales 5·1% Therefore the differences in the incidence of illegitimacy between Catholic and Protestant countries are hardly significant

Age of Unmarried Mother at Maternity

A composite picture of the unmarried mother, according to popular imagination, would reveal a drab pathetic-looking girl in her early teens or a brassy young madam in her middle twenties This sort of picture, however, does not accord with the facts The Registrar-General's statistics (table V) showing the age of mothers at maternity reveal that, of all those aged less than 20, 1 in 5 is unmarried, but, except these and the 25–29 age-group, the percentage distribution of maternity cases in the different age-groups are about the same for legitimate and for illegitimate births The difference in the 25–29 age-group (21·6% illegitimate, 32% legitimate) is probably due to the fact that, with the widespread practice of birth control in marriage, conception is delayed and the peak of fertility not reached until the age of 25–29, whereas, for unmarried mothers, the peak age for fertility is 20–24

The impression that, for the most part, unmarried mothers are relatively young is to some extent explained by the survey undertaken by the Church of England Moral Welfare Council (1954) This revealed that 3543 of 7057 applicants (more than 52%) were aged less than

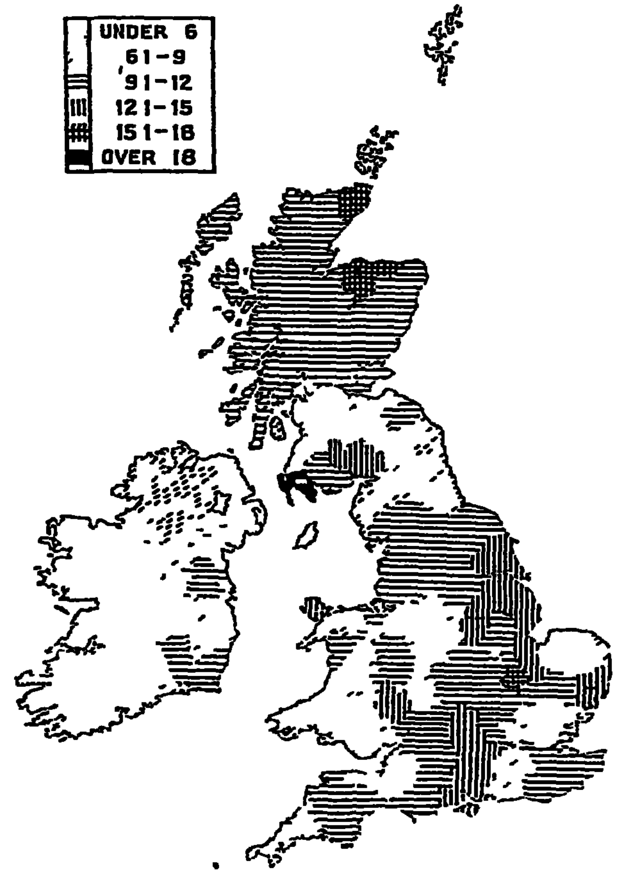

Fig 1—Number of illegitimate births in 1953, per 1000 unmarried women aged 15–44

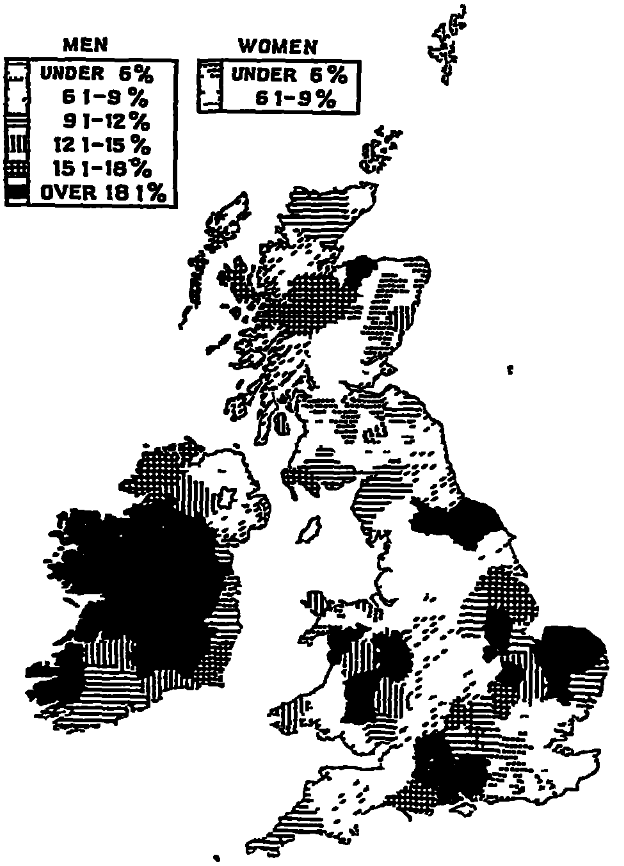

Fig 2—Surplus of unmarried adults aged 16–44 in 1953 excess expressed as percentage of total for both sexes

TABLE V—AGE OF MOTHER AT MATERNITY

(From Table AA, Registrar General's Statistical Review of England and Wales, 1953)

Age of mother (yr)	Legitimate	Illegitimate
	Total	Total
Under 20	25 058 (*3 8%*)	5359 (*16 5%*)
20–24	185,106 (*28 5%*)	9659 (*29 7%*)
25–29	209 669 (*32 1%*)	7028 (*21 6%*)
30–34	144,779 (*22 2%*)	5860 (*18 0%*)
35–39	65,253 (*10 0%*)	3215 (*10 0%*)
40–44	20 603 (*3 1%*)	1291 (*4 0%*)
45–49	1381 (*0 2%*)	87 (*0 2%*)
50 and over	20 (*0 003*%)	4 (*0 01*%)
All ages	651,869	32,503

22 Of the 3436 unmarried mothers dealt with by the National Council for the Unmarried Mother and her Child in 1953 (unpublished) 48 8% were aged less than 22

This is confirmed by my own unpublished findings in more than 11,000 requests for advice in 1953, of which 662 (6%) related to "illegitimate births and pregnancies" About 60% of those giving information were aged less than 22

These facts indicate that it is usually the younger unmarried mother who needs and seeks the help of moral-welfare agencies It is therefore extremely important to recognise that the young woman who comes for help has additional problems to those of the older unmarried mothers Failure to make the important distinction between unmarried mothers who seek the help of a specialised welfare agency and those who do not tends to vitiate the findings in otherwise useful case studies On common sense grounds alone it must be assumed that the girl who overcomes her difficulties with the loving support of her own family and friends is likely to have a vastly different psychology to the unhappy pregnant girl rejected by her family and left to face her troubles as best she can

In considering the problems of unmarried parenthood it cannot be emphasised too strongly that, apart from the unmarried mothers aged less than 20, who represent 1 in every 5 maternities, and, to a lesser extent, those aged 25–29, who represent 1 in every 30 maternities, the age distribution of mothers is about the same for legitimate and for illegitimate maternities Most of those who seek the help of specialised welfare agencies are aged less than 24 and therefore can be regarded as having very special difficulties, which often include the broken home and mental instability

Civil Status of Unmarried Parents

There is relatively little reliable information about the civil status of unmarried parents Apart from the single girl who becomes pregnant after brief sexual contact with a casual acquaintance, there are those who are betrothed but cannot marry the girl whose fiancé is unexpectedly posted overseas, and the girl whose lover may be a married man waiting for a divorce There are also the particularly tragic situations of the married woman who becomes pregnant by a man other than her husband, and the widow who, often as a result of loneliness and misery, enters into an undesirable sexual relationship

The Church of England Moral Welfare Council (1954) reported that 6006 (84 3%) of 7194 mothers were single, 903 (12 3%) were married, 180 (2 2%) divorced, and 105 (1 2%) widowed In my unpublished study of the "advice column" 68% were single, 16% married, 1 6% divorced, and 3 3% widows In 11 1% of cases civil status was not stated

The Registrar-General's reports unfortunately do not distinguish between the child born to a single woman and the child (possibly one of several) born to parents who live together in a permanent relationship although not legally married to each other An equally grave omission in these reports is the complete lack of information about the putative father

In the Church of England Moral Welfare Council's (1954) survey of 4880 cases available for analysis 1698 (35%) of the putative fathers were married men This proportion is amply confirmed by the finding that, of the 3436 cases dealt with by the National Council for the Unmarried Mother and her Child, about 48% of the putative fathers were married This helps to explain the lack of relationship between figs 1 and 2 showing the geographical distribution of illegitimacy and counties with a surplus of single men and women

The fact that probably more than a third of putative fathers are married men, who are therefore not free to marry, is of considerable significance in assessing the value of current theories regarding illegitimacy It is important also to appreciate the extent to which illegitimate children are born to parents who, although living together in a more or less stable home, are not married to each other

Spence et al (1954) reported an illegitimacy rate of *58 7 per 1000 at Newcastle upon Tyne Less than half* of these infants were first babies, and the mothers' age distribution differed very little from that of mothers giving birth to legitimate babies The explanation was that many of the second and third infants were born to parents living in established, if unofficial, families, 27 (30%) of the children alive at the end of the study were living with both parents as members of unofficial families

Nisbet (1954) reported that, of 200 illegitimate births inquired into by the Kilmarnock health department, the number of mothers cohabiting was 60 (30%)

It therefore seems reasonable to assume that about 1 in every *3* illegitimate births are to women, probably in older age groups, cohabiting in a more or less permanent relationship Although it is impossible to make any accurate estimate, probably most of these women have more than one child by the same father

TABLE VI—ILLEGITIMATE BIRTHS AND SOCIAL CLASS

(From Table 28, Registrar-General for Scotland Report 1954)

Social class	1	2	3	4	5	Not stated
Total live births	3509	9341	49,041	14,372	11 871	1614
Total illegitimate live births	3	132	994	1089	345	4
Percentage	0 08	1 40	2 02	7 50	2 90	0 24

Cooper (1955) emphasises that, although 34 of the 55 illegitimate children referred to by Spence et al (1954) were living more or less stably with their parents, in 32 cases the conditions of living were most unsatisfactory *10 children belonged to problem families, 12* were in severely overcrowded homes, and 14 lived in dwellings classed as unfit for human habitation There is little evidence to suggest how far this sordid picture is common to all cohabiting parents It is, however, probably true that the habit of living together without the sanction of marriage is common among problem families, the sort that give rise to many of the insoluble social difficulties of a large city

An opportunity to test Cooper's (1955) impression was presented by the 1954 Annual Report of the Registrar General for Scotland, which classifies live births by social class, the age of the mother, and the number of previous children (*table* VI) *Illegitimacy is rare in social* classes 1 and 2, the professional and intermediate occupations, and uncommon in class 5, the unskilled, where most of the problem families would be grouped Illegitimacy is commonest in class 4, partly skilled workers The same class distribution occurs for illegitimate stillbirths Thus suggests that the sordid conditions described by Cooper (1955) are probably not common to the majority of illegitimate children, at least in Scotland Unfortunately this valuable table is not included in the England and Wales report

Two other facts are also of importance (1) divorce, which would have enabled at least some of these parents to marry each other, was not until fairly recently (Legal Aid and Advice Act, 1949) available to those with limited means, and (2) efficient contraception is used far more frequently among the upper social classes (Lewis-Faning 1949), this may tend to reduce the number of illegitimate maternities among the higher income groups

Abortion

Similarly, although it is exceedingly difficult to prove, it is also possible that abortion is practised more commonly among women in the higher social classes The extent of abortion in Britain was officially estimated as 110,000–150,000 every year The report of the Inter-departmental Committee on Abortion, 1939, states (p 107)

> "Although by far the greater number of criminal abortions undoubtedly occur among married women, there is reason to suppose that the proportion of pregnant unmarried women who undergo criminal abortion is higher than the proportion of pregnant married women who resort to it"

Young (1954), in the U S A, states that "very few unmarried mothers apparently consider the possibility of abortions" Since this is contrary to experience in this country, I obtained, with the kind assistance of Mrs Alice Jenkins, of the Abortion Law Reform Society, a fairly authoritative statement on the incidence of abortion among single women in the United States The Planned Parenthood Federation of America stated "that a conservative estimate of criminal abortions in the United States is 330,000, roughly a thousand a day," and "unmarried girls are reported to consist of 10 per cent of the abortionists' clientele" According to this estimate about 100 criminal abortions are done each day in the U S A on single women As Young (1954) recognises the girl who procures an abortion does not present as an unmarried mother, and her psychological picture would be different

Discussion

The data presented here, however, do not appear to support the view that unmarried mothers as a whole, apart from having conceived out of marriage, differ in important respects from other women of the same age and social class If there is a difference it is in their relatively higher reproductive capacity, which has a physical as well as a psychological basis

I could discover no evidence to support Young's (1954) conclusion that "in the majority of cases the unmarried mother wants a baby, specifically an out-of-wedlock baby without a husband" The fact that at least a third of the putative fathers are married does not necessarily indicate a widespread desire to avoid marriage Many unmarried parents marry as soon as they are free to do so In 1953 there were in England and Wales 2369 and in Scotland 469 re-registrations of births under the Legitimacy Acts The Church of England Moral Welfare Council's (1954) survey showed that within a year the mother had married the "putative father" in 299 (3 6%) cases and "another man" in 119 (1 4%) cases

It is evident that not enough is yet known about unmarried parenthood for the formulation of considered theories or generalisations about it Nor are the unmarried mothers or putative fathers a homogeneous group of people with special social and psychological characteristics in common The greatest need at present is for further detailed studies of them

Apart from the vital considerations of the health and welfare of mother and child the investment of public funds on preventive work and research would eventually considerably reduce public expenditure In 1953 the National Assistance Board found that more than 20,000 unmarried mothers received allowances amounting to £2,359,000 yearly—a subsidy from public funds of £2 5s a week for each mother

The already influential work of the National Council for the Unmarried Mother and her Child and the welfare work of the non-sectarian religious organisations, such as the Church of England Moral Welfare Council, should receive official recognition and financial support In cooperation with these agencies medical officers of health and Universities should be encouraged to undertake well planned and coördinated research A useful approach might be to finance experienced social workers with anthropological training so that they could take up several years' residence in selected areas where the illegitimate birth-rate is traditionally high This would enable them to obtain first-hand and intimate knowledge of the operation and influences of the particular cultural patterns By establishing herself as a member of the community the research-worker, together with the health visitors, could better safeguard the health and welfare of mother and child and direct the attention of the community towards appropriate preventive measures

Conclusion

I have tried to bring together here some of the facts which provide the foundation for discussing unmarried parenthood

Most of the vital pieces of this jig-saw puzzle are missing, and only a very few of the available pieces fit together Accordingly there is a natural impulse to ignore the facts and to retreat into the comfort of our own prejudices and fancies, where we can conveniently fashion the facts to suit our personal needs But the problem will still be there and, although we may not see it, children will continue to die needlessly, many of those who survive will be miserable, and the unmarried mother will suffer for our indulgences as well as her own The aim to save these children so that they may live without a sense of guilt and shame will best be served when we face the facts and understand their meaning better

ODONTOLOGICAL CENTENARY

In October 1856, the 'memorialists' a small group of ardent, pioneer practitioners in dental surgery, led by John Tomes, who had failed to win the support of the Royal College of Surgeons for their repeated demands, met in Old Burlington Street and founded the Odontological Society of London On Jan 5, 1857, they held their first formal meeting of the society which some fifty years later, as the section of odontology, became one of the founder sections of the Royal Society of Medicine

The centenary of the founding of the Odontological Society was celebrated on Jan 4 by a dinner at the Royal College of Surgeons, under the chairmanship of Mr J A S Wright, president of the section of odontology, when Miss Patricia Hornsby Smith parliamentary secretary to the Ministry of Health was the principal guest

In a speech proposing the health of the section, Sir Zachary Cope spoke of the founders' persistent, far sighted, and eventually successful efforts to establish dental education on a firm and independent basis and dental surgery as a specialisation in its own right

SOIL, FOOD, AND HEALTH

A Public Declaration

THE following statement has been sponsored by medical and dental members of the council of the Soil Association (8f, Hyde Park Mansions, Marylebone Road, London, N W 1) and has been signed by more than four hundred members of the medical and dental professions The signatories include general practitioners, consultants, medical officers of health, and university professors

THE TEXT

In 1939 the Local Medical and Panel Committee of the County of Cheshire, representing some six hundred general practitioners, issued a Medical Testament[1] This testament, in our considered opinion, ranks as a historic document It declared forthrightly that, whilst good progress had been made towards the second objective of the National Health Insurance Act of 1911, in so far as postponement of death could be regarded as evidence of the cure of sickness, no such progress could be observed in the attainment of the first objective—presumably of at least equal importance—the prevention of sickness It affirmed that the basis of such prevention was essentially nutritional, its signatories stating that their daily work brought them repeatedly to the same point "This illness results from a lifetime of wrong nutrition"

MEDICAL SIGNIFICANCE OF THE ORGANIC MOVEMENT

The Medical Testament was an inspiration to many forward looking people, in particular Sir Albert Howard and Lady Eve Balfour, pioneers of what has come to be known as the Organic Movement It confirmed and enlarged their own experiences in the field of agriculture and constituted a notable contribution to the thesis for which the movement stands and for which considerable support has been gained in many different parts of the world in the last ten years

This thesis is, basically, the concept of organic wholeness applied to the vital relationships between soil, plant, animal and man, with special reference to health It envisages health as a positive process which is profoundly influenced by the interdependence of all life, primarily through the medium of nutrition It postulates, therefore, that the key science is the somewhat neglected one of ecology—the study of the relationships between living creatures and between such creatures and their environment

In all these respects the Organic Movement represents a marked departure from the present trend towards the increasing fragmentation of science, the piecemeal application of science through technology as expediency dictates, and the unceasing struggle to deal with the ever changing manifestations of individual diseases, whether in plants, animals, or humans On the other hand, its tenets are in keeping with the definition of health propounded by the World Health Organisation—namely, "a complete physical, mental and social well-being, and not merely the absence of disease or infirmity"[2]

Moreover, the concept of nutrition as a flow of nutrient materials from the soil through plants and animals to humans has been strongly reinforced by recent researches in the field of human metabolism These, by the use of isotopes to trace the passage of food constituents through the body, have demonstrated that all human tissues undergo constant renewal

It follows that the integrity and biological quality of the nutrient materials used for this renewal are of first rate importance to health; and that the extent to which they are influenced by agricultural practices becomes a matter of great practical significance to the medical and dental professions Yet, so far as we are aware, the only scientific studies hitherto attempted in this field are those being conducted at the Haughley Research Farms in Suffolk These are maintained by the Soil Association as a purely voluntary effort to enlarge our stock of knowledge, independently of State aid or commercial patronage

The Haughley experiment is designed to investigate and compare, on a farm scale—and therefore on a realistic basis—the cumulative effects of three contrasted types of soil management on (1) the fertility of the land, (2) the nutritional quality of its produce, and (3) the health and productivity of farm animals fed continuously and exclusively on that produce

There are three sections or "farms," side by side on land of similar type, managed as follows

(*a*) An "organic" section of 75 acres on which fertility is maintained by leys (temporary pastures) and compost made from its own animal manure and vegetable wastes—i e, it is self contained

(*b*) A "mixed" section of 75 acres on which fertility is maintained by leys and its own animal manure, supplemented by "artificial" chemical fertilisers—i e, similar to orthodox farming practice

(*c*) A "stockless" section of 32 acres treated with chemical fertilisers only, and green manuring—i e, it represents the purely chemical concept of soil fertility

Since 1947 the "organic" and "mixed" sections have each maintained its own herd of Guernsey dairy cattle (the third-generation heifers bred on the farm are not yet coming into milk) and its own flock of poultry, the foundation animals and birds having been carefully selected from common stocks by independent experts

Having first been laid out (as regards soil management) in 1940, this experiment has the unique advantage of having undergone a preparatory period long enough to permit previous treatment of the land to be largely written off and subsequent cumulative effects to develop With this prepared material as a starting-point, scientific studies were begun in 1952 under the direction of Mr R F Milton, PH D These, which have gradually been extended in scope, include

(1) Detailed chemical and physical analysis of soil samples taken monthly from each field, including some trace mineral analyses

(2) Detailed analysis (including some vitamin assessment) of the field produce and of the milk and eggs

(3) Close observation of the health and behaviour of the farm animals

Results to date indicate[3]

(*a*) That there are very considerable fluctuations (which would not of course be shown by the usual annual sampling) in the levels of available plant nutrients according to the season and the system of management

(*b*) That in terms of nitrogen and humus contents—a fair measure of soil fertility—the "organic" section is improving while the other two sections are deteriorating

(*c*) That there are changes in soil structure, attributable to systems of management, which may well become significant in effect

(*d*) That the recovery, through crops, of the plant nutrients applied as fertilisers to the "mixed" and "stockless" sections is extremely low

(*e*) That the dry matter content of crops on the "organic" section tends to be higher than that of crops on the other two sections

(*f*) That the dairy herd on the "organic" section yields consistently more milk, with a higher solids content, than does the herd on the "mixed" section, and has so far shown a better breeding record

(*g*) That there is preliminary evidence of lower vitamin and trace elements in the produce from the "mixed" and "stockless" sections than in that from the "organic" section

[1] Cheshire Panel Committee Medical Testament Nutrition Soil Fertility, and the National Health *Brit med J* 1939 i, suppl p 157

[2] From the first of the Nine Principles of the World Health Organisation

[3] Summarised reports 1952, 1953, 1954 are available from the Soil Association

DECLARATION

We, the undersigned medical and dental practitioners, desire to reaffirm the conviction expressed by the Cheshire Panel Committee regarding the intimate connection between nutrition and health

We deplore the fact that, in the seventeen years that have elapsed since the publication of the Medical Testament so little has been done to implement the avowed intention of the National Health Service Act, 1946, in regard to the prevention of disease the more especially in view of the steadily increasing incidence of degenerative diseases, which contrasts markedly with the mastery achieved over infectious and inflammatory diseases

We would draw attention to the fact that during this period, we and a growing number of professional colleagues, together with many veterinarians farmers, horticulturists, and others, concerned with the health of livestock and crops, have become increasingly aware of the fundamental importance of the relationships between soil plants, animals, and man

We believe that the task of preventing disease is best envisaged as the enhancement of positive health and that, in this task, nutritional research should play a leading part

We believe further, that any such research which fails to take into consideration the soil on which the food is grown, and the farming practices involved, must be accounted incomplete This belief is in no way modified by the fact that much food is subjected to chemical and mechanical treatment after it leaves the land, flour being an outstanding example Such treatment also is of deep concern to us, though it cannot be discussed here We would, however, observe that it may well depress still further any reduction in food values that may be attributable to current agricultural practices

We would urge, therefore, that any research designed to discover which methods of soil management result in the highest food values should receive our professional support, and that such research should be both comprehensive in scope and of long term—extending over several decades rather than years

We note that apparently the only such research at present in progress is that being conducted at the Haughley Research Farms already mentioned and consider that it would be a tragedy if this one experiment, with its prepared material, were to be brought to a premature end—as seems only too possible—for lack of public interest and support It has now reached a stage at which its further extension, especially on the scientific side, should yield an increasing dividend of knowledge, but the enthusiasm of the Organic Movement, which has already accomplished so much, cannot be expected to undertake unaided the heavy financial commitment involved

In support of these contentions we would cite Sir John Charles who, in his 1952 annual report as chief medical officer, Ministry of Health,[4] referred to the uncharted fields exploration of which would surely reduce the burden of the curative services and who called for research into the causation of the so called chronic diseases Sir John referred also to the activities of the Medical Research Council indicating that the fields of research lying open to the investigators would not be narrowly limited

We would cite also the chief medical officer for the Department of Health for Scotland who in his 1955 annual report,[5] states that "at later ages the increasing threats of coronary thrombosis and cardiovascular disease, and of cancer of the lung, especially in males, maintained their position as major health problems in which no clear lines of medical attack have yet emerged"

In our view the recent suggestion of the importance of the essential fatty acids to the circulatory and nervous systems and to the carcinoma barrier points to the kind of knowledge which is becoming essential to us as practitioners

We therefore, call upon those responsible for the finance initiation, and guidance of medical research to consider the urgent need for ecological research, linking the basic approach to human nutrition with the origins of human food and, in particular, to assist the one experiment already in progress in this field

Medicine and the Law

A Missed Fracture

A WOMAN of 82 fell at an old people's home The doctor at the home, and the casualty officer at the hospital to which she was sent, both diagnosed a fractured arm, but failed to diagnose a fractured hip She was sent back to the home and died some days later At the inquest[1] the casualty officer said that he had not made a very thorough examination He knew she had been examined by a doctor at the home The coroner criticised him, saying that it would be as well if casualty officers "carried out their duties with a completeness the public has a right to expect"

Public Health

Miniature-radiography Survey in Bootle

IN the winter of 1955–56, an intensive survey was undertaken in Bootle by the Liverpool Regional Hospital Board's mass-radiography service[2] The object was to determine the extent of the reservoir of tuberculosis

One mobile unit was used continuously and two others occasionally each unit worked independently All streets were visited systematically, there was one open session each week for doctors' cases, volunteers, and contacts, factories offices, and schools were visited Before and during the survey a propaganda campaign was carried on Leaflets were displayed in public offices and cinemas and distributed in schools, the local newspapers carried advertisements, the film *Also Coming Shortly* was shown in the cinemas, talks were given to women's organisations, loudspeakers were used, and members of the Women's Voluntary Services canvassed from door to door, explaining the campaign and offering to act as baby-sitters while mothers were being radiographed

Bootle contains about 61,000 people over the age of 11, in the survey 22,340 were examined, including 13 901 residents of Bootle Many of the population work in Liverpool and could not be examined The response of industry was about the same as in 1954, nearly all eligible school children attended the open sessions started well, but fewer and fewer volunteers attended partly because they preferred to wait for the street sessions the street sessions started well, but attendances fell in bad weather and around Christmas On the whole, the response was much better than in 1954, and might have been better still if the survey had been held in summer if the site for the open session had been more convenient, and especially if two mobile units had been used exclusively for the street examinations early in the survey, leaving the school and office examinations till later This sequence was recommended after a similar survey in Salford[3] Efforts to follow those who failed to attend for further examination were not very successful

In the survey 32 people were found to have tuberculosis that needed immediate treatment, and 580 to have tuberculosis that was suspected, healed or needed clinic supervision The number of Bootle residents in the street-to-street group found to have tuberculosis needing immediate treatment or close clinic supervision represented 4 92 per 1000 people examined 12 patients with carcinoma, 98 with bronchiectasis, and 332 with cardiac abnormalities were found

---

[1] *Manchester Guardian* Jan 4

[2] Liverpool Regional Hospital Board an Intensive Mass Radiography Survey carried out in the county borough of Bootle By T R ROBERTSON and J A RUSHWORTH

[3] See *Lancet* 1954 ii 1172

Many of the tuberculous had not been examined before and many had unilateral disease It is concluded that "the method of street to street and house to house survey has proved its value as a case-finding method"

Statistical Review of England and Wales

In part I of his Statistical Review for 1955[1] the Registrar-General records the detailed statistics of deaths from all causes and notifications of infectious diseases in that year, by age, sex, area of residence, and time of year

Deaths—The death rate of 11 7 per 1000 living was the highest since 1951, but the rate was lower in 1955 than in 1954 for all age groups except 5–19, 55–64 (where the rate was unchanged), and 65 and over

Deaths in early life—The stillbirth-rate (23 per 1000 total live and still births) was the same as in every year since 1948, except for 1953 when it dropped to 22 The infant mortality rate of 24 9 per 1000 related live births was the lowest ever recorded in this country The Northern region and Wales had the highest infant mortality rates (31), while the Eastern, South Western, and London and South Eastern regions had the lowest (21)

Tuberculosis—Deaths from tuberculosis (all forms) numbered 6492 in 1955 compared with 7897 in 1954 Since 1949 deaths from tuberculosis have declined by more than two thirds

Cancer—Compared with 1954, there was an increase of 941 in deaths from cancer of the lung, which formed 31% of all male deaths from cancer but only 6% of female deaths from cancer

Coronary heart disease—Deaths attributed to this cause have risen by almost 50% since 1949, reaching 44,256 for men and 26,341 for women in 1955

Bronchitis and pneumonia—The number of deaths certified as due to pneumonia was practically equal for the two sexes, but more than twice as many men as women died from bronchitis (19,294 males and 9499 females), of these, 16,519 male and 6607 female deaths were assigned to chronic bronchitis

A New Way With Chilled Meat

The idea of transporting beef carcases from abroad at temperatures high enough to avoid freezing the carcase and yet low enough to retard microbacterial growth has always been attractive As long ago as 1875 chilled beef was shipped across the North Atlantic the artificial cooling being applied at first by ice and thereafter by mechanical refrigeration The Argentine became Britain's main source of imported meat, for the sea journey took only fifteen days compared with some thirty days from Australia

The biggest difficulty in exporting chilled meat from Australia was that during the voyage mould developed on the surface of the meat, and for many years Australian beef imported to Britain had to be consigned in the hard-frozen state Many attempts were made to avert the development of mould on chilled meat during long voyages formaldehyde was tried but was eventually forbidden as constituting a danger to public health, but more recently it has been shown that the storage life of chilled beef is considerably prolonged if the atmosphere in the ship's hold contains about 10% of carbon dioxide—a method that has been used commercially

The arrival in Liverpool recently of the first shipment of Australian chilled beef kept fresh by ultraviolet rays has created considerable interest, for the cooling chambers of any ship can be fitted quickly and cheaply with the necessary apparatus Hitherto ultraviolet light has proved fairly effective in sterilising air, but less effective in the case of food because of its negligible penetrating power The opinion of the meat trade and of the consumer as to the quality of chilled beef so imported will be awaited with interest

In England Now

A Running Commentary by Peripatetic Correspondents

THE postman, whose sample-laden calls are causing distress and inducing black thoughts about the drug trade on Saturday mornings (*Lancet*, Jan 5, p 44), can be troublesome on other days of the week to those who work, as I do, in the second-floor front of an old London house and resent every foot-poundal expended in climbing the stairs And so can other people delivering goods But there is a remedy Buy from a fishing-tackle shop a wooden reel, 10–12 yd. of no 6 square-plaited flax line (20 lb breaking strain), and a small leaden weight Fix a spare front-door key to the end of the line with the weight threaded on an inch or so above it and a strong spring paper-clip riding loosely above that When the bell peals, and/or the knocker bangs, lower away, meantime engaging the caller in conversation from above By the time he has realised where the voice comes from the key is dangling at his hand at lock-level He then opens the door, disengages the key, and deposits the parcel on the floor while I reel in If a signature is required the book (or document) is fixed to the line by the paper clip In the absence of a supply of tiny parachutes a further "reel out" and "reel in" is needed, but the improved technique which comes with practice makes this task both agreeable and quickly executed In the spring, when the vine burgeons on the first-floor balcony, I plan to have a proper "spinning" rod (small) lest entanglements threaten our local blackbird's autumn food supply I will think of my peripatetic colleague at breakfast time on Saturdays, which is only fair, since I am a medical consultant to a firm of pharmaceutical manufacturers which doesn't post samples on a Friday—at least I don't think it does

* * *

A letter addressed to me at the "Royal Informary" called out some pleasing overtones I was not sure whether a delicate compliment was being paid to our skill in teaching, or whether a snook was being cocked at our disciplinary ward-sisters But my chief once again displayed his realism by suggesting that an informary was a place where forms were filled in At any rate we all felt in better form, and after all even Shakespeare and Freud scorned not the pun

* * *

In future, when people suggest that in technology and science we lag behind our cousins in the United States, I shall take comfort in the story of the gallant New Jersey firemen and their struggle to insert a fire alarm through a 730 ft pipe The pipe pursues an awkward twisting course beneath the New Jersey Turnpike, on one side of the highway lie the Lafayette Estates (a new housing scheme), on the other the Woodbridge fire-station The Woodbridge firemen, conscious of their responsibilities for these new residents, are anxious to connect the estate with the fire-station Oblivious, or perhaps suspicious, of the march of science, they have turned for help to the animal kingdom By means of a light harness they attached a piece of string to a rat and urged the rodent into the pipe But though eight rats have now entered the pipe none has emerged at the other end After brief explorations six have returned to base two, it is feared, have died in an S-bend Anxious to give the rats every help and encouragement, the firemen next procured a pet mongoose to keep them company The mongoose, Pop by name, seems to be an infuriating animal While acting as pace-maker he scuttled gaily through the whole length of the pipe But when he too was provided with harness and offered the responsibility of a length of string he never penetrated deeper than 300 feet

In their troubles the firemen have had the sympathy and interest of what the *New York Times* (Jan 6) describes as "an aroused public" It is true that some experts, such as the assistant dean of the Brooklyn Polytechnic Institute and the head of the department of civil engineering at the Massachusetts Institute of Technology, have tamely suggested such gadgets as an electric mouse or a ball under pressure But other citizens have shown more imagination Mrs Richard Fondiller, for instance, suggested that a large beetle with butter on its nose would follow the scent of the butter through the pipe (This method she says was successfully used, according to a classical tale, for transmission of a rope to a prisoner in a high tower) Artie Gildener (aged 14) proposed, rather unkindly, that a bottle of ammonia should be opened near the end of the pipe after a rat has entered Another kindlier but anonymous man suggested toasting cheese at the exit

---

I don't know what the firemen are going to do, but I shouldn't be surprised if some of them are out looking for beetles

* * *

The jargon used by music critics is not in the same class as that of wine-tasters, but it is sometimes unsettling The other Sunday, relaxing from the busy immunisation programme of the previous week, I tuned in to *Music Magazine*, and immediately learned that a symphony by Stravinsky was built round a "germ theme" Moreover, this germ theme, I was told, consisted of B C G repeated frequently An extract was then injected intra-aurally, with a multiple-puncture technique In the circumstances there was surprisingly little local discomfort, but my composure was gone The therapeutic value of music is well known, but its prophylactic virtues are obviously fraught with controversy

* * *

He is an old man of 81 and very thin I asked whether he had been losing weight "I don't rightly know, but I *think* I must have When they gave me a bath yesterday I floated"

DEATH IN THE THEATRE

So this is death,
And God's white angels stand around the bed
Angels One at my feet, one at my head,
And two And two How does the rhyme go on ?
Angels But were they angels, Luke and John ?
Why are they wearing masks ? When did I die ?
I can't draw breath
" Just go on breathing, ' who said that, and why ?
Why must I breathe, why, now that I am dead ?

Thus the patient,
Waking a moment from premedication
But not long sentient

A stranger entered
Angels indeed ? Mock angels to his eyes,
In baggy booted amateur disguise,
Whose backs, in place of wings,
Revealed a row of clumsily tied strings
And gaps And other gaps the stranger
Impartially observed, glancing behind
Façades into recesses of each mind
Trivial, self centred,
Earthbound expressions of exasperation
Hidden behind masks ignored the danger
Of unseen observation

The anæsthetist
Was thinking, we'll not finish off this list
By lunch time , nothing left to eat
But tepid scraps A houseman cursed the heat
A nurse was thinking deeply of injustices,
The surgeon of œsophageal varices
(Routine appendicectomies are waste of time)

Time ? Twenty minutes past the hour ,
The angels are passing over Make haste
Hush
And the mock angels thoughts were quieted,
Stilled by the silence of the silent rush
Of unseen wings A pulse flickered rioted
and ceased
The sombre silence stiflingly increased ,
None dared draw breath

Only the stranger
Watched with delight, ironical and mild
Death smiled

Letters to the Editor

THE FUTURE OF NURSING

SIR,—It was with real regret that many nurses read Dr Thomas Anderson's letter (Jan 5), though perhaps we can exercise some measure of understanding when we remember that his main experience of nurses and nursing has been in the field of infectious diseases—a field now rightly regarded as part of a comprehensive nursing education

In the experience of many nurses, medical men can be divided into two broad categories (*a*) those who regard nurses as their colleagues in rendering service to the patients , and (*b*) those who regard nurses as the handmaidens of the doctor, requiring only that they know (preferably from him) how things are done and never inquiring why they should be done in this way The first category is anxious to help nurses establish and maintain standards of patient care, realising that the nurse who knows both how and why is a better all round nurse and colleague The second category looks at nursing and nurses from one angle

The shortage of woman-power, the increased need for nurses in a national health service, and the very large number of callings now open to women, means that nurses are drawn from all socio economic levels with various degrees of intellectual capacity and differing educational background Inevitably, we are going to recruit more and more of the girls who only want to know how, as opposed to those who want to know how and why and who will form the leaders in the profession This latter group must be given a preparation which will enable them to exercise more than adequate supervision so that the patient comes to no harm If this is what Dr Anderson calls "officer class," then we do not quarrel , after all, we do not attempt to run the Services without officers, so why do we think it is possible to do so in nursing ? Perhaps Dr Anderson thinks of the doctors as the officers, and of the nurses as the other ranks

The letter goes on to say that nurses should develop along the "line of the needs of the doctor and of the needs of the public whom we both serve" Do the majority of doctors really accept this ? Medicine is diagnosis and therapeutics, but nursing has a unique function

> "The nurse is temporarily the consciousness of the unconscious, the love of life for the suicidal, the leg or arm of the amputee the eyes of the newly blind We do not do *to* patients as if we were their custodians, nor do we do *for* them as if they were our dependents We do *with* them leading them on to increasing self direction '

The nurse renders her service to the patient, not to the doctor

In so far as the *examinations are concerned*, they are the responsibility of the General Nursing Council, and, if Dr Anderson wants to find fault with them, he should register his protest in the right quarter

His recent experience with the sister tutor seems to have surprised him, but it would not have surprised a nurse What makes Dr Anderson think that he or the chest physician sees things from the point of view of the social worker or the occupational therapist ? Social work, occupational therapy, and nursing are all professions in their own right with disciplines and skills which play no part in the curriculum of the medical student

Finally, may I add that the *Lancet* Commission on Nursing was not set up to "allow the medical profession to redefine the kind of nurse this country requires" The nursing profession is quite capable of doing this, and would regard any other profession laying down its standards and its code of ethics as little short of impertinence

Royal College of Nursing,
Scottish Board
44, Heriot Row Edinburgh

MARGARET C N LAMB
Education Officer

SIR,—I have read with interest the correspondence following your annotation (Nov 24), having myself trained as a nurse before starting on a medical career

The statement of policy of the Royal College of Nursing reiterates the problem of providing enough nursing care of a high standard in the country's curative and preventive services, but their answer appears unrealistic and in some ways regressive They envisage a horizontal expansion to equip enough people to do the nursing, and a vertical expansion to provide teachers and leaders The result would be a hierarchy rather than a "team" Admission to training for each grade is to be based on "qualitative selection including entrance tests and assessment of individual capacity" It is said to be hard to select medical students, then surely to choose (at the age of 18) embryo leaders and teachers for a vocational profession will be even harder A profession offering opportunities for advancement is surely more attractive than one which offers only the chance of selection to some grade, especially when the grade may bear the title "assistant nurse" Would it not be better to give all nursing candidates a short basic training in the care of patients after which they could either remain practical nurses or take more advanced courses in special nursing ward management, teaching, or administration ? This scheme would do away with the invidious distinction between hospitals suitable for training S R N s and those suitable only for training assistant nurses An "officer class" which has not risen from the ranks may not understand the problems of those who provide the daily nursing care

The R C N report makes no mention of less drastic changes which might increase what they call nurse power Educated girls will not choose a profession in which they are cut off from a normal cultural and social life, as are student nurses, by the irregular and unpredictable hours of work The shift system as tried successfully during the war can be the answer to this problem, for, properly organised, it gives predictable off duty without detriment to the standard of nursing care

The R C N give no reason for the categoric statement that no one under 18 should be included in the nursing team In support of Dr Ritchie Russell's contention that most girls are ready for hospital work at 17, it may be mentioned that fifteen years ago some general training schools did accept student nurses at 17 (and perhaps they still do) The professional life of nurses is usually short, being terminated by marriage, and the year gained by an earlier start would do much to relieve the shortage

The problem of the supply of nurses is one not simply of recruitment but also of preventing wastage Any profession mainly staffed by women must be realistic enough to accept and cater for marriage and motherhood if it is not going to lose some of its most valuable recruits A recent advertisement, for a responsible person to look after two children and to do light housework part-time was answered by 3 S R N s and 2 nurses on the supplementary register All said they would like to nurse if they could find suitable posts, now that they had homes and families With imagination and a less rigid approach, surely these mature women could be used in the nursing services

Cardiff JULIA FOURMAN

SIR,—It is obvious from this correspondence that there is a pressing need for nurses and doctors to meet and discuss problems common to them both on an equal footing It is as ridiculous to say that a nurse must always be subordinate to a doctor as it would be to suggest that she should always act independently of a doctor The care of patients is a far more complex problem than the carrying out of doctor's orders, and nurses, or at least some nurses, must be trained to meet the wider concept of total care of the patient

How many doctors would wish to be responsible for the way a ward sister runs her ward ? Or for the training of nurses in the art of nursing ? These are not properly the functions of a doctor, any more than venepuncture and taking the blood pressure are properly the functions of a nurse But if doctors are willing to allow competent nurses to carry out such things, can they expect them to regard themselves as wholly subordinate ?

Nursing, in the sense of caring for the sick, can be quite independent of medical care it can be good, bad, or indifferent, so that the patient can be well treated medically but badly nursed Similarly, the patient can be well nursed but inadequately treated Indeed, one of the criticisms of nursing today is that nurses are carrying out so many "treatments" that they have no time to devote to nursing This criticism only applies at the bedside, however, and at the bedside care can be carried out, under the direction of trained people, by those with little basic training It can be adequate, but it need not be we must not allow ourselves to be persuaded that sick people can be well nursed by untrained or partly trained or unintelligent people An intelligent well taught person can do everything better than a stupid or untaught one, and this applies to nursing no less than to any other job

So far from lowering our standards of basic training, they should be raised, teaching must be improved so that everyone who wishes to learn and is capable of learning does so, training must be organised so that trainees learn what they need when they need it, and at their own pace With regard to the qualified nurse, it is becoming increasingly obvious that basic nursing training is not sufficient to enable anyone to take higher posts without further specialised preparation This applies from the ward sister level upwards Now there is no *reason whatever why such preparation* cannot be at university level, the arts of administration, of teaching, of organisation, the knowledge of psychology, of personal relationships, of educational methods, can all be learnt at a university Tutors are trained in this way and there is no reason at all why ward sisters and matrons should not be In fact, I would go further and say that they must be if, in future, hospitals are going to be places where sick people get better, and if the wider needs of the health services of the community are to be met

The old pernicious practice of promoting people simply because they had given ten or twenty years' service must certainly go, and go quickly Long years of idling away time in the same job, doing the same things year after year, is not experience, nor does it teach anyone anything Nurses in future must move about more, think more, do more, and be prepared to undergo further education in preparation for higher posts, and doctors must realise that in the higher posts they will find men and women they can regard as useful and reliable colleagues fully able to realise the responsibilities we must all share in the future health of the community

Doctors who are interested in nurse-training would be well advised to read and study carefully the proposed new syllabus of the G N C for mental-nurse training They will find here a curriculum that offers opportunities for a basic training within the capacity of any normally intelligent and interested person, yet capable of providing a foundation on which further studies can be built—a curriculum which can turn out trained nurses able to care well for sick people, yet also suitably prepared for gaining further knowledge at a higher level

It is surprising that doctors should consider themselves in a position to criticise nurse education Many nurses could make pertinent criticisms of medical education, except that they do not consider they have any right to do so. Perhaps what is really needed is a freer exchange of opinion and ideas on both sides; if the participants did not benefit, the likelihood is that the patients might.

RETURN TO PLANNING

SIR,—Your leading article of Jan. 5 contains a statement that cannot be allowed to pass unchallenged. You say "... while a salaried service would abolish financial competition altogether." Surely this is quite untrue. Would you say that there is no financial competition to reach high rank in the Army or Navy—or, for that matter, in our own profession among members or those seeking membership of hospital staffs where payment is in the main by salary, with the possible addition of Merit Awards?

There are, of course, many other possibilities to be considered; but if there is to be a "return to planning," which is the title of your article, the idea of a salaried service cannot be summarily dismissed on the grounds you state. The precise opposite is the truth. One of the great advantages of payment by salary is that it could offer the best possible type of financial competition in that the reward could be based on the quality of the work done rather than on the number of patients on a doctor's list—two things that so often compete in inverse proportion.

A few years ago[1] you were good enough to publish my views as to how a salaried service might provide a solution to our problems. Very briefly, one visualised general practice in the National Health Service organised in groups working from health centres, some members of each group adopting special interests and their salaries mounting to match their special skill, qualifications, and experience. In the higher grades these should certainly conform to those paid to members of hospital staffs. Vacancies in the service would be filled by a system of advertisement and application supported by testimonials. Advancement would depend on the judgment of professional colleagues instead of, as at present, the chance of popular favour or density of population.

This indeed would present a most radical change and a complete break from the past. It would offer a new prospect to those joining the profession and might help to solve our registrar problem. One feels, therefore, that young men should have a greater voice in our counsels, and planning should not almost entirely be in the hands of the elderly who have in the main retired from practice.

I am acutely aware of the many difficulties and dangers that such an idea would present and the intense opposition it would arouse. Nevertheless one must surely admit that far from abolishing competition for financial and professional advancement it would foster it in an extreme degree and this is one of the greatest points in its favour.

Plymouth

W. A. LISTER

THE Rh BLOOD-GROUPS

SIR,—Dr. Wiener, in his letter last week, again demands not only the retention of his Rh-Hr nomenclature but also the abolition of the far more convenient CDE terminology. While nobody could deny the value of Dr. Wiener's work in this field, he is now rather in the position of a Chinese philosopher who has written a great work in the language he knows best and stubbornly opposes its translation into Western languages, arguing that it is up to the Western countries not only to learn Chinese, but to abandon their own languages in favour of it.

Dr. Wiener takes you to task for "serious errors of commission and omission" in your editorial, but the "evidence" he himself produces will not stand examination. His method of arranging it by comparing dissimilar tables can equally well be used in reverse. One takes phenotype and all possible genotypes for one's own system but only the "most likely genotype" for one's opponent's. Thus:

Blood	*Most likely genotype*
Putative father's	R^1r
Mother's	rr
Child's	R^0r

Such a report could mislead one into believing that the Rh-Hr tests exclude paternity. Yet in the CDE notation the same case might be reported as follows:

Blood	*Phenotype*	*Possible genotypes*
Putative father's	CcDee	CDe/cde, CDe/cDe, cDe/Cde
Mother's	ccddee	cde/cde
Child's	ccDee	cDe/cDe, cDe/cde

Obviously the CDE tests do not exclude paternity. If Dr. Wiener is going to omit the word "possible" before "genotype" he is going to find paradoxes everywhere. The -D- pedigrees quoted could have been expressed equally misleadingly in Rh-Hr notation, and could have shown mothers of genotype R^0r having children of genotype $R^1\mathfrak{R}$. In both these examples it is possible to "prove" by Dr. Wiener's own reasoning the superiority of the CDE system.

Pathology Laboratory,
Essex County Hospital,
Colchester.

J. W. NICHOLAS

UNILATERAL ELECTRO-SHOCK

SIR,—Not to harm (*primum non nocere*) is a cardinal maxim forcibly brought to mind by electro-shock treatment. It has prompted me to try the effect of applying electrodes to one side of the head only.

The dominant side of the brain was avoided as a precaution against possible damage to the speech area. The shock was therefore administered on the right side of the head in right-handed persons and on the left in the left-handed. To limit the area exposed to direct stimulation, the electrodes were placed on the scalp over the precentral (motor) gyrus in about its middle third (i.e., Brodman's area 4b) or lower (area 4c).

The smallest response has been a slight upward movement of the contralateral eyebrow; the next a contraction of the contralateral muscles of the face as a whole. In other cases the head was turned to the side opposite to the site of the shock and the contralateral platysma muscle contracted; in others still, the convulsive movement involved the contralateral arm and even the leg.

Sometimes, despite the limited area of stimulation, the convulsion would spread to the whole body. Nevertheless the muscular response was in general more restricted and milder than in trans cerebral shock.

Practical points worth noting are:

(1) A small sand pillow is placed beside the head on the side opposite that on which the shock is to be given. Though as a rule the turn of the head is barely perceptible, there may be a jerk. In any case, support is needed to withstand the slight pressure of the electrodes.

(2) For the headgear, the standard horseshoe shaped plastic holder may be broken in the middle for greater freedom of placement.

(3) 'Cambridge Electrode Jelly' is rubbed into the hairy scalp at two selected points—about an inch apart—in preparation for placing the electrodes. The electrode pads, soaked in saline, are squeezed beforehand so that the saline does not run.

A muscular relaxant (suxethonium bromide, 'Brevedil E') and an anæsthetic (thiopentone) are used in the accepted manner.

---

[1] *Lancet*, 1951, ii, 876.

Where the muscular contraction is limited to a flicker of half the face, the risk of fracture of spine or limb is eliminated, and even when the fit has involved a limb or limbs there has been no obvious damage Breathing was resumed far more quickly than after the standard bilateral shock—perhaps because the diaphragmatic area was missed altogether or because only half the diaphragm contracted As anatomically the thoracic representation in the brain lies higher up, in Brodman's area 4a, the pulse often remained full and regular In the most favourable cases, the cerebral representation of the abdominal cavity should be missed, with less risk of abdominal complications

Patients awoke within a few minutes of the shock Many became lucid and orientated very quickly, and those who had previously been puzzled by retrograde amnesia following bilateral electro shock seemed delighted by the extent of their memory of events just before unilateral shock The patients soon became ambulant and, in many cases, cheerful Recovery room activities took much-less nursing time for the group of patients as a whole and the ward resumed its normal appearance much more quickly

In over 100 shocks, the only hazard noted as peculiar to the unilateral method has been slight singeing of the hair where the saline on the electrode pads has run or where a bridge of jelly has contaminated the hair between the pads

Clinical results, so far, appear to justify continuing with the method of unilateral electro shock

Deva Hospital, Chester ISAAC FROST

DANGEROUS CONTAMINANTS IN STORED BLOOD

SIR,—It is no use Dr Discombe saying (Jan 5) "I maintain that the safest procedure is to use pilot bottles and to refrain from entering the main bottle until it is actually to be used" and thinking he has thereby solved all the problems of blood transfusion My department cross matches about three thousand bottles of blood each year, and that experience might lead me to be as dogmatic as Dr Discombe and maintain that pilot bottles are useless and misleading and should not be permitted

In practice neither statement would stand up to examination in detail, and arguments such as those used by Dr Discombe will do nothing to make transfusion safer All we can do is to establish the general principle that transfusion is a hazardous procedure and that therefore each laboratory must devise a method of providing blood that reduces the hazards to a minimum if they cannot be abolished. My own view is that to do this involves taking all samples for cross matching from the bottle that is to be infused, that whatever appropriate tests can be done in the time available should be done, and that all this must be done by trained staff who are doing enough of it to remain trained and expert

In such circumstances Dr Discombe's conclusion from Dr Drummond's figures that 5 1% of entered bottles are contaminated in hospital laboratories must be wrong In this laboratory all blood is looked at for gross contamination by examining a film of the sample that is being used for cross-matching, and at the same time, and all bottles that have been entered and are to be re used are re entered and cultured My technicians would not agree with, and Dr Discombe's can hardly be complimented by, the suggestion that a few minutes spent on examining a film renders them liable to make a mistake in ABO grouping In any case contamination is so rare that one might be tempted to accept Dr Discombe's dictum and neglect the procedure, but we do not because we are prepared to take all steps we can to reduce the hazards

We believe we have seen more deaths after transfusion from clinical misjudgment as to the need for that procedure than from bacterial contamination or serological incompatibility Wise and restrained use of blood by clinicians and a good system of laboratory control by trained personnel (only), including bacteriological examinations and no pilot tubes, and we are doing the best we can

Surrey D STARK MURRAY

NEUROTIC PARENTS

SIR,—I have read Dr J G Howells's article on Day Foster-Care and the Nursery (Dec 15) with the same interest as all his previous excellent publications Such work is indeed rare among children's psychiatrists, whose daily routine usually prevents research But this very lack of parallel investigation should make us the more careful about accepting too readily the apparent implications of a pilot experiment and rejecting the pioneer work of J Bowlby and others which has led to a healthy change of attitude in child welfare workers throughout the world If, as Dr Howells mentions, the Report of the Children's Department for 1955 shows that only 1 in every 200 children is now in institutional care, this is due very largely to the drastic change of policy inspired by Bowlby's report on Maternal Care and Mental Health Howells's work is an antidote to uncritical acceptance of the theory of maternal deprivation, but it is less contradictory to Bowlby's researches than it appears It seems to me that he has, in fact, unwittingly confirmed what Bowlby teaches by showing[1] how separation from the mother was longer among the 37 neurotic children than among the healthy ones, and that a father can prevent nervous symptoms in a child by acting as (in Bowlby's sense) a mother substitute His observation that, because of poor substitute mothering, hospital admission is the most traumatic experience for children supports Bowlby's views rather than his own insistence on the benefits of day foster care Furthermore, the value of Bowlby's work lies in the prevention of affectionless and chronic neurotic adolescents and adults, and not, as Howells and Layng[2] imply, in any claim that maternal deprivation causes maladjustment in childhood itself Bowlby has never failed to emphasise the need for removing the child from an emotionally unhealthy home, but he has emphasised how harmful separation from parents can be It would be wrong, I think, to weaken belief in our present tendency to keep families together, and to encourage even "unwanting harsh, rejecting and hurtful parents" to seek substitute care too readily in every case we should first try by intensive psychiatric social work or the help of a family service unit, to change their attitude

Bowlby's work remains unchallenged and proves that satisfactory adult affectionate social relationships can be learnt in infancy only through one's love relationship with one's own mother As Dr Howells says, substitute care must supply "warm mothering," and "many well intentioned people drawn to child care" lack the ability to supply this Even more serious, and surprisingly often overlooked, is the persistent insecurity of any child "in care," because of continual changes of personnel and the ever possible rejection by a foster parent The real parents, even if they refuse to acknowledge the child and stay bodily away, remain to him all his life "my father and my mother" Are we not overstating the damaging effect of a neurotic home when we form our views on our rather limited child psychiatric experience? Hardly any family is without

ENURESIS

SIR,—I was much interested in the article by Dr L A Nichols (Dec 29) He has said nothing to change my view that in these cases the personal influence of the doctor is one of the most important factors Certain of his theoretical and practical statements I feel are incorrect May I offer a few comments and criticisms ?

(i) It must be accepted that enuresis is socially undesirable This statement may seem trite, but in my experience it is all too common to hear that a doctor has said "Don't worry, mother, my own son had it until he was 14" Furthermore, loss of bladder control is not thought abnormal in all societies for example, Margaret Mead[1] tells us "When an infant urinates, or defecates, the person holding it will jerk it quickly to one side to prevent soiling his or her own person This jerk interrupts the normal course of excretion and angers the child In later life the Arapesh have notably low sphincter control, and regard its loss as the normal concomitant of any highly charged situation"

(ii) Arnold Gesell and his colleagues[2] have described the natural history of bladder control and pointed out that "the whole problem of bladder control is so charged with developmental factors in normal as well as deviated children, that they should have primary consideration both in interpretation and in treatment The culture is inclined to be too meddlesome and too emotional "

(iii) The causes of enuresis have often been examined Stockwell and Smith[3] found a psychological cause in 50% of the cases, and of these 88% were improved or cured by psychiatric help, including environmental changes A further 37% were ascribed to physiological variations of neuromuscular function This group is the one that would respond best to renewed habit training and the use of drugs The remaining 13% had some organic basis for their enuresis This is in my view abnormally high It is the general consensus of opinion that urological lesions are found in perhaps 5–7% of children with enuresis Therefore Donald Paterson's dictum[4] ought always to be in our minds "Before starting the treatment of enuresis it is absolutely essential that organic disease should be ruled out" This is very difficult without too many complicated investigations, and a good rule is that of M F Campbell,[5] who says that if an intensive medical or psychological course of treatment is unsuccessful after, say, 2–4 months' trial, the child is entitled to a complete urological examination Anyway, admission to hospital for a fortnight's observation would be helpful because spontaneous remission is usually seen in the ward in cases of psychological ætiology (providing the intelligence quotient is not too low)[6]

(iv) We still have the special problem of adult enuresis, and whilst Thorne[7] and Cohen[8] consider this a symptom of a fundamental defect in the central nervous system most studies have concluded that in the non organic cases it is a symptom of a more generalised psychiatric disturbance

(v) Even if we discount the adult enuretic and separate the 5% or so of "organic" cases, we are left with the fact that "nocturnal enuresis is probably the commonest habit disorder"[9]

Despite these criticisms therefore, Dr Nichols's determined attack on the problem is to be applauded and his paper welcomed as a stimulus to general practitioners to take an interest in such a difficult and common disorder

SIR,—The method described by Dr Nichols is likely to prove useful But I want to point out an almost ubiquitous fallacy with regard to the management of enuresis Dr Nichols writes

> One cannot emphasise too strongly to the parents that the desire to be dry is much greater in the child than in the parents Being an enuretic is no bed of roses

This, however, neglects the existence, in many cases, of a need for self-punishment Also many children will confirm, and even explain at length, that both the wetting and the stay in a wet bed are to them a pleasurable sensation which they have no real wish to forgo The gaining of control over desires or functions is never pleasurable, and is always done in exchange for love —from parents or others

Hospital Derby

D J **Salfield**

SIR,—You are to be congratulated on publishing the article by Dr Nichols not only because articles by general practitioners are all too rare in our overspecialised medical journals, but also because his article is full of excellent and practical advice His way of handling this common and distressing complaint is one which I, as a child psychiatrist, heartily endorse

Drugs are of limited use, and should only be considered as adjuvants It might be said that Dr Nichols has oversimplified the problem, and that in some cases enuresis is only a symptom of a deeper disturbance, but in the great majority of cases his approach, which is basically one of explanation and encouragement, is the best one—both to this and other problems in childhood His article also has a bearing on the whole question of psychotherapy in general practice, which is at last beginning to receive the attention it deserves

THE GREATER MEDICAL PROFESSION

SIR,—Recent comment in your journal concerning the almoner's future status within the "greater medical profession" appears to me to be based on a misapprehension of some importance both to the patients and to ourselves Implicit throughout what has been written is the assumption that the doctor has the power to stand with his patient in a place apart until he decides otherwise None should question the rightness of this while it concerns only the patient's body and sometimes his troubled mind It is, I suggest, a false assumption directly it is held to include the social emergencies consequent upon illness If the doctor fails to make this distinction events may move out of his control to the detriment of his patient

The social consequences of illness impinge with varying force on people other than the patient, and while they, and the patient, will wait with unquestioning thankfulness for the doctor's advice upon medical matters, they will frequently take the initiative themselves in an effort to relieve the anguish of his circumstances Appeals for help and advice are frequently made to the hospital almoner because she is known to stand close to the doctor on whom dependence is placed She has, I suggest, in consequence, not only the duty to obey the doctor's instructions with the greatest possible care but also the heavy responsibility of advising him on her own initiative upon matters about which her knowledge and experience may be wider than his own Only when the almoner accepts scrupulously that her final duty to the patient is confined within the doctor's instructions to herself and when the doctor recognises his almoner as a specialist with her own smaller but individual responsibilities can the patient's social difficulties adequately be relieved

CUSHING'S SYNDROME WITH CARCINOMA OF BRONCHUS

SIR,—In the article by Dr Harrison and others (Jan 5) I am quoted as having reported a similar case This is not so, and in fact my only reference to such a patient was during a discussion on the relationship of 17-keto genic steroids to surgery at a meeting of the Surgical Research Society in Birmingham last year The patient in question was in fact under the care of Dr H P Brody at the Sheffield Royal Infirmary, and the findings have been submitted for publication by members of his staff

When no actual contact has been made between an author and the person he is quoting, the words "personal communication" are not, I think, the most suitable form of reference

Royal Infirmary, Sheffield, 6

R P JEPSON

PSYCHOTHERAPY IN GENERAL PRACTICE

SIR,—Your leading article of Dec 29 prompts me to describe my own voyage into this ill charted territory

I had for some time been distressed by the large amount of "neurosis" with which I had "to contend" in my practice Eventually I had to admit to myself that my understanding of these patients was deficient, and my management of their cases inadequate It was evident that if I were going to bring any relief to their suffering —and my own distress—my education and experience had to be supplemented in some way I knew of no postgraduate courses for this type of work, and was unfortunately unaware of Dr Balint's general practitioner discussion groups at the Tavistock Clinic I had already been practising untutored trial and error, and felt that it was fraught with danger

I had, however, been making use of the services of one of the Middlesex County Council's psychiatric social workers, Mr Eugene Heimler, and had been gratified by the progress which several of our patients had made We felt that it would be interesting to observe the effects of close collaboration between us, both on the patients and on myself I believed that my main disability was a lack of psychiatric orientation, and hoped that the psychiatric social worker (P S W) would help me achieve it

One afternoon each week was set apart for a joint "mental health session" with the P S W at my consulting room We decided to exclude children (for whom we both felt further experience would be necessary) and *to include the following groups of patients*

1 The overtly "anxious," in difficulties either at work or at home

2 Those presenting mainly with somatic symptoms where I had taken reasonable steps to exclude physical illness and where environmental stress was known or suspected

3 Those with a hysterical prolongation of an originally physical illness

4 Suspected psychotics

5 Psychiatric cases requiring supervision by a general practitioner

I found that I did not have to "sell" the idea of this joint approach to the patients in group 1, who were mostly only too pleased that someone was prepared to listen to their tale of woe In groups 2, 3, and 4, this was often not the case, for though I felt that a psychogenic ætiology existed, the patients often had other ideas The greatest difficulty at this point was to avoid being drawn into battle with the patients, but rather to offer them a reasonable alternative to repeated "reassurance" and unending medication I went to war less frequently as I gained experience, but it certainly took time

In the joint session, we attempted to consolidate the good rapport which I had tried earlier to establish A genuine interest in the patient's difficulties and a desire to help are the most desirable instruments At first I was little more than an onlooker, the P S W doing most of the work, and I realised more than ever how little I knew and how much there was to learn We started off by inviting the patient to discuss his symptoms, his difficulties, or anything about which he particularly wished to talk It was evident that the most important qualification was to be a good listener

I noticed that diagnosis presented little difficulty to me, but this had previously been exasperating, for it had not been a step towards active treatment These interviews, however, added another element to my clinical diagnosis a psychosocial diagnosis is a summary of the patient's potentialities in a given environment, taking into account his normal and abnormal psychological reactions

With the development of a good rapport, the patient became more receptive to any interpretations which we might give We tried to crystallise the problem, and to show him possible connections between his symptoms and any environmental factors to which he was responding, according to the pattern of behaviour which was peculiar to him We aimed to help him understand his reactions and the reasons for them, hoping to change his attitude, we also recommended alteration of the environment when this was both practicable and desirable Thus, when a harassed mother was receiving psychotherapy her child might be placed in a day nursery for part of the time, or a home help obtained Some patients improved with merely one interview, usually of about 45 minutes, while others needed several, those who failed to improve were referred to the psychiatric clinic, or were seen by a psychiatrist at home In cases of suspected psychosis a consultant's opinion was always sought We often saw the patient's relatives, giving them some explanation of the disability and advice on general management

The table shows the effect of treatment on the first 43 patients studied The numbers are small and several patients are still under treatment and may be regraded at a later stage The grading of the response is based on my subjective impressions

Group	No of cases	Response to treatment		
		No improvement	Partial adjustment	Satisfactory adjustment
1 (anxiety)	20 (*47 %*)	4	9	7
2 (psychosomatic)	13 (*30 %*)	5	3	5
3 (hysteria)	2 (*5 %*)			2
4 (? psychotic)	4 (*9 %*)	2	2	
5 (aftercare)	4 (*9 %*)	2	2	
Total	43 (*100 %*)	13 (*30 %*)	16 (*37 %*)	14 (*33 %*)

This experiment, which has been in progress for a year, has undoubtedly had its effects upon myself With the help of the P S W, I have gained some insight into normal and abnormal mental mechanisms This has helped me in the routine conduct of my practice, and has amply repaid the time spent on the afternoon sessions In many instances I can treat the less disturbed patients satisfactorily during my normal surgery hours I am also gaining insight into my own emotional responses to my patients, and some whom I previously would have felt as a source of irritation and frustration I now regard in true perspective as troubled men and women in dire need of help

Although the journey is just begun, I have at least gone some distance in the right direction, instead of wandering aimlessly in the wilderness There are some, working in general practice, who have already emerged as masters of this art, and it is to them that we must look for guidance and teaching

My thanks are due, above all, to Mr Eugene Heimler, for his capable navigation throughout the year, to Dr A C T Perkins, county medical officer for Middlesex, for his cooperation, to Dr G S Wigley, his deputy, for encouragement and advice, and to Dr Colman Kenton, the regional psychiatrist for helpful criticism The Middlesex County Council, naturally, accepts no responsibility for the views expressed in this letter

London N 13

NEVILLE DAVIS

SHORTAGE OF RADIOGRAPHERS

SIR,—I wish to comment on one or two important points in Mr Baxter's letter (Dec 22)

An Industrial Court award has recently been made granting radiographers an increase of salary of less than 10% This award raises the maximum salary of a superintendent in one of the largest X-ray departments to £850 per annum—a maximum no radiographer can hope to reach under the age of 45 It will be appreciated that the superintendent of a busy department requires certain medical knowledge, in addition to great technical and organising ability This is especially true in one of the many busy departments where there is no full time radiologist The superintendent radiographer's maximum salary of £850 is quite inadequate and compares most unfavourably with, for instance, the corresponding salary of £1025 of the chief laboratory technician

The salaries of the lower grades of radiographer are, of course, correspondingly more meagre, and considerably less than equivalent grades in other ancillary departments Here are some figures for comparison

	Junior	*Senior*
Physiotherapist Occupational therapist	£462 10s–£537 10s	£520 10s–£580 10s
Radiographer	£420–£485	£485–£570

The physiotherapists are at present negotiating an improved salary-scale

Unless a radiographer is lucky enough to have one of the very few tutor posts, she receives no payment for lectures given to radiography students There is likewise no reward for a radiographer attaining her fellowship In short, there is very little incentive for anyone to take up radiography, or even to stay in the profession

It seems incredible that the Industrial Court should see fit to make such a poor award in view of the grave shortage of radiographers, and the insistence in the recent M R C report on the hazards to Man of Nuclear and Allied Radiations [1] that repeat X-ray examinations must be avoided by careful work in the first place, by responsible technicians

The recent findings in Oxford, on leukæmia in children who were X-rayed in utero,[2] surely prove the necessity for maintaining a high standard in the radiography profession I feel that any person handling X-ray apparatus should be suitably rewarded for her skill as a technician and her responsibility to the public in using a potentially dangerous X radiation

Radiodiagnostic Department
Hammersmith Hospital,
London W 12

C J MYDDLETON

SIR,—May I comment on the views expressed by Dr G H Illingworth (Jan 5)?

The dissatisfaction with salaries is not by any means confined to a "few male radiographers"—attendance at any meeting of radiographers will prove conclusively otherwise

The statement in regard to educational requirements is again evidence of an ill informed opinion, the standard required is very reasonable, is accepted by radiological bodies and the Ministry of Health, and is consistent with the requirements of other similar medical auxiliary bodies A reasonable level of technical knowledge would seem desirable when one considers that a girl may have to operate and handle a rather complicated X ray machine, worth many thousands of pounds—apart from the fact that such a machine may be lethal to a patient in unskilled hands

Restriction to approved training schools can only *raise* the standard of radiography, and therefore lead to more efficient radiology Any radiologist worthy of the name would decry the 'hole and corner' training to which many student radiographers were formerly subjected

The Society of Radiographers has, if anything made entry and qualification easier in the past few years by (1) broadening the educational requirements, (2) increasing the scope in the examination papers, and (3) increasing the breadth of training and thus ensuring a better comprehension of the subjects

To say that there are only two essentials in the production of a radiograph is ludicrous, and the statement that physics, maths, and English are not essential strikes at the roots of the whole system of technological education, for its acceptance could lead to the production of a race of moronic button pushers

I believe that most radiologists and radiotherapists would agree that a superintendent radiographer is an essential member of the radiographic team, and only by having complete harmony between radiologist and superintendent (male or female) can an X-ray service or treatment be fully efficient

Furthermore, has Dr Illingworth considered how few X-ray departments have a full-time radiologist who can also function as a full time radiographic superintendent? It would seem evident that Dr Illingworth would prefer his department to be staffed by "unqualified X-ray assistants," whom we hear may infiltrate understaffed departments up and down the country

Many radiologists and the Society of Radiographers deplore this possible state of affairs, which could only lead to a lower standard of radiography and radiotherapy—at a time when many authorities, single and corporate, are demanding the intelligent use of radiation and are stressing the hazards of incompetency

To my knowledge over many years, the Society of Radiographers has striven to maintain the highest possible standards, consistent with radiological requirements, and only by the continuance of this endeavour can radiology be assured of the most efficient contribution of British radiography (possibly the best in the world) in the common cause of medicine

Cardiff

E R HUTCHINSON

AN ERROR TRACKED TO ITS SOURCE

SIR,—The silent intervals in this correspondence are a little reminiscent of my attempts to play chess by post with a Russian friend living in the Ukraine before the revolution of October, 1917

In my original letter,[1] I sought information as to the source of a phrase, in an instructive and interesting article by Dr Carstairs and his colleagues,[2] attributed by them to Galen I hate to throw any doubt on Dr Carstairs's claim,[3] but is it not possible—nay, probable—that the phrase in dispute is Burton's own and not Galen's?

In the *Anatomy of Melancholy* [4] we find the following passage

> "Besides, it [exercise] expells excrements by sweat, and other insensible vapours in so much that Galen prefers Exercise before all Physick, Rectification of diet, or any regiment in what kind so ever, 'tis Natures Physician"

As a marginal note alongside the passage, Burton quotes Galen's *De Sanitate Tuenda* liber I, in which work can be found passages which could justify his summing up

According to R M Green's translation of this work,[5] Galen says

> "And it is clear, even at this age, how much our nature is associated with exercise, for, not even if you shut them up somewhere, could you prevent children from running about and frolicking like colts and calves For in all animals nature is enough to incite the impulses appropriate for health and safety"

Later in liber II [6] Galen considers what is the distinction, or degree of distinction, between work, exercise, and movements, exercise to him connotes vigorous movement, and therefore, to him, the work of "those who dig, and those who reap and those who ride" is synonymous with exercise

ANTIBIOTICS AND IMMUNITY TO VIRUSES

SIR,—Immunity to many viruses has been considered to be a premunition resulting from persistence of the immunising virus in the cells of the host As some viruses appear to be sensitive to antibiotics, it would be of interest to know whether the present widespread and somewhat indiscriminate use of antibiotics does not destroy these persistent viruses, and, with them, the immunity they confer The implications are obvious

Amoebiasis Research Unit
Durban South Africa

R ELSDON-DEW

PUERPERAL TETANUS

SIR,—I was interested to read the article by Dr Ramsay and his colleagues[1] At the African Hospital, Zomba, Nyasaland, there have been two cases of puerperal tetanus in the past two months The first patient died, but the second recovered Case 1 I did not see, but case 2 I attended

CASE 1 —On July 30 the patient had a normal delivery in her village, but on the following day was admitted to hospital with a septic perineal tear By Aug 8 the patient's condition appeared to be satisfactory and she was discharged from hospital The following day (Aug 9) she began to have stiffness of the neck and jaw She did not return to hospital until Aug 14 when she had pronounced trismus and neck and back rigidity and generalised muscle spasms She was given 100,000 units of tetanus antitoxin intravenously and 10,000 units into the vulval wound At the same time she received 600,000 units of procaine penicillin intramuscularly and she was sedated with paraldehyde given rectally She died on Aug 16, two days after admission

CASE 2 —On Sept 26 the patient gave birth to a normal live baby The delivery was conducted by her mother in a small hut in a village, naturally enough with no aseptic precautions From the patient s description the delivery seems to have been uncomplicated with nothing to suggest a retained placenta On Oct 5 (i e, nine days after the birth of her child) she was admitted to hospital complaining of pain and stiffness of her jaw, back and neck On examination there was risus sardonicus and masseteric spasm the gap between the teeth being $^1/_2$ in when the mouth was open to its fullest In addition there was opisthotonos with severe neck and back rigidity At the time of admission there was only slight rigidity of the abdominal muscles, but by the following day these were extremely rigid Despite her condition she was fully conscious and cooperative, though any disturbance such as moving the patient or even tapping the bedclothes induced generalised muscle spasms Owing to the frequency of meningitis in these parts I performed a lumbar puncture and withdrew colourless fluid containing 2 lymphocytes per c mm and 30 mg protein per 100 ml and so excluded that possibility However, unlike Dr Ramsay and his associates, I have no pathological confirmation of my diagnosis

The following treatment was given (*a*) 200,000 units of tetanus antitoxin intravenously on admission, and then (on the supposition that *Clostridium tetani* organisms might still be forming toxin) 25 000 units intramuscularly every four days, (*b*) procaine penicillin 600,000 units daily, to avoid pulmonary infections, and for its specific effect, if any, on the organisms, (*c*) paraldehyde for the first three days given in the form of 10 ml intramuscularly six hourly and thereafter 30 ml in 300 ml of saline given rectally six hourly for the next seven days, (*d*) for the first five days all feeding was done through a Ryle's tube, giving 5% dextrose and saline milk, and eggs

After seven days there were no further muscle spasms By the tenth day the abdominal rigidity had disappeared and there remained only slight masseteric spasm and neck rigidity By the fourteenth day the patient could open her mouth fully and touch her chin on her sternum On Oct 29 (i e twenty four days after admission) the patient was discharged apparently fully fit, feeding her baby with a bottle

On clinical grounds I felt very certain of my diagnosis, but I must confess that I was rather surprised to see the patient recover Perhaps the incubation period was fairly long, but whatever the reason this recovery would indicate (*a*) that puerperal tetanus is not quite so rare among primitive peoples, and (*b*) that, although muscle relaxant drugs with assisted respiration may be the treatment of choice, in centres where this is not possible the older methods of treatment may still be effective

INTERMITTENT POSITIVE PRESSURE AND SPEAKING

SIR,—Intermittent positive-pressure artificial respiration is often used in conjunction with a tracheotomy tube fitted with an inflated cuff There is then no current of air through the larynx and the patient cannot attempt to speak Sometimes, the inflated cuff is allowed to leak so that the patient may be able to use the leaking air for speech, but there are disadvantages and even dangers in this arrangement

We have fixed a small tube, about 3 mm bore, to the convexity of the tracheotomy tube so that its open end lies in the trachea above the inflated cuff Through this tube a gentle stream of air or oxygen flows and passes up through the larynx so that the patient can modulate it and attempt speech, yet the lower trachea remains completely sealed off

Now, through the cooperation of a lady recovering from respiratory paralysis who is using intermittent positive pressure, we know that the arrangement can work About 15 cm of water pressure is needed, and 4 litres per minute permits an intelligible whisper though 6 litres per minute is needed for real speech The "air" can be taken from an oxygen cylinder, or an aquarium aerator pump will supply this order of flow There must be a simple safety blow off to prevent excessive pressure It may be necessary to seal the tracheostomy wound with 'Vaseline' gauze though we did not have to do this for the patient mentioned If the patient has the use of her hands it is quite easy to put the air flow under her own control

We recognise that the method has limitations and it may have some dangers If there be severe laryngeal involvement, speech would be impossible even with the provision of the artificial air stream Mucus always tends to accumulate in the glottis and trachea above the inflated cuff and the "speech air stream" at first blows this up into the mouth but this is not harmful We think it might be dangerous to introduce such an air stream in the early days of a tracheotomy before the planes of the neck had become sealed off, because of the risk of surgical emphysema if the tube became misplaced

However, even if the power of free communication can be returned only to a small proportion of these unfortunate patients, it would be worth while

Perhaps this simple idea has not yet occurred to other doctors and they may wish to work upon it We would, of course, be most interested to hear whether they find it practical

X RAYS AND LEUKÆMIA

SIR,—The fascinating arguments put forward last week by Dr Court Brown and Dr Doll seem to be based largely on the invalid "assumption of a simple proportional relationship between dose and effect"

No generalisation about dose effect relationships can be better than an approximation, but the relationship of simple proportion is not acceptable even as an approximation Pharmacologists assume as a first approximation that Fechner's law is obeyed Expressed in a form applicable to the present problem it is "The intensity of the effect is approximately proportional to the logarithm of the dose" Fechner died in 1887

Let us hope, Sir, that in these atomic times your correspondents have made a quantum jump from a wrong assumption to a right conclusion

London, W 1 G B LOXTON

UNIVERSAL-JOINT CATHETER CONNECTIONS

SIR,—Swivelling catheter mounts are not new but, so far as I know, are not at present obtainable in this country

Their need became apparent to me in the treatment of respiratory paralysis, where the conscious patient is turned, with resultant twisting of the cuffed tracheotomy tube

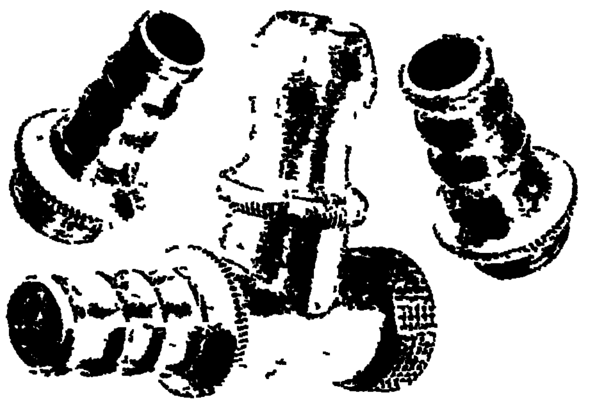

Fig 1

Connections like those shown in figs 1 and 2 have been used for about a year at the National Hospital and elsewhere and in every case have won the warm approval of the patients There has been no damage to trachea or to larynx

In anæsthesia there are many advantages in having an easily movable mount Interchangeable ends can be fitted for differing sizes of tube (fig 1)

The construction is so simple as to need no explanation The screwed portions are left loose and tapped with a fine thread, and are airtight even under the arduous conditions of pressure respiration

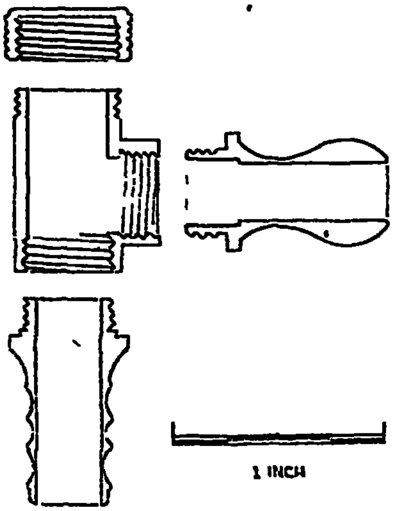

Fig 2

Theoretically a curved form gives a better flow, but this advantage is minimised by unavoidably increased size Therefore, for practical and structural reasons, the right angled shape was adopted

My thanks are due to Messrs A Charles King, 27, Devonshire Street, London, W 1, who coöperated so ably in the production of these mounts

National Hospital,
Queen Square London, W C 1 R ATWOOD BEAVER

MEAN VENOUS PRESSURES IN THE FIRST HOURS OF LIFE

SIR,—I was interested to read the paper by Dr Bonham Carter and his colleagues (Dec 29), because I hoped to find some useful information relating to hyaline membrane in the newborn

Like many others, I have believed for some time that the pulmonary syndrome of the newborn—or, as Edith Potter has called it, pulmonary congestive failure—results from a disturbance in the pulmonary hæmodynamics at the time of birth I have so far seen no reference to the brilliant experimental work of Born et al[1] in Oxford who have recorded pressure changes in the circulation of newborn lambs

From their work we learn that if the cord is ligated before respirations begin, profound asphyxia results and there is a great increase in blood pressure, partly because of asphyxia (operating through chemoreceptors) and partly because the systemic circulation of the lamb is cut off from the low peripheral resistance of the placenta Since the ductus arteriosus is open, this high pressure is communicated to the pulmonary artery The transitory pulmonary hypertension together with anoxia may perhaps be responsible for the changes in the lungs in pulmonary congestive failure, and the systemic hypertension and the anoxia may conceivably account for the occasional cerebral complications in these infants

Delay in pulmonary ventilation is common in premature infants and, though it is an increasingly common practice to wait for the cord to cease pulsating before ligating it (for quite other reasons), it must still be very common for the placental circulation to be excluded before breathing is established In cæsarean sections it is usual for the surgeon to sever the cord immediately so that he may have the baby out of the way often before the infant has started to breathe

I suggest that such an unphysiological state of affairs is likely to lead to a lesser circulation failure primarily, and systemic venous congestion may be delayed, if it occurs at all If this is so, it is not surprising that the venous pressures recorded by Bonham Carter et al in many of the babies with respiratory distress were low, since all except seven were taken within the first 6 hours after birth In none of the eight fatal cases were readings taken after 5 hours, though all survived for 18 hours or more Born et al found that the pressure in the inferior vena cava actually fell after the cord was tied despite a steady rise in pressure in the aorta, pulmonary artery and left atrium at this time (possibly because the large placental venous return was cut off)

I am putting these hypotheses to the test of clinical observation Meanwhile I suggest that it would be a good plan to delay ligation of the cord for as long as possible in premature deliveries and cæsarean sections, and, when breathing is delayed, to administer intragastric oxygen immediately in order to prevent too drastic a fall in the arterial oxygen content following loss of the placental circulation

TREATMENT OF SORE THROAT

SIR,—In their comprehensive trial of intramuscular penicillin in the treatment of acute sore throats, Captain Brumfitt and Captain Slater (Jan 5) set out to answer the question whether it is reasonable to exhibit penicillin routinely in all such cases Nevertheless they have not committed themselves to an answer

Because of our inexact understanding of the processes causing illness, it is often difficult to reconcile the scientific findings of one aspect of an illness with the clinical results as a whole The fact that no infecting organism could be demonstrated in 32% of the cases does not necessarily exclude streptococcal infection, for there are many examples in medicine where the infecting organism, although present, cannot always be isolated (Pyelonephritis is but one such example) Also, can "normal bacterial flora" always be dismissed as non-pathogenic? I have had cases of tonsillitis where culture has resulted in predominant growth of such an unlikely organism as *Escherichia coli*, and staphylococci of various types are not uncommonly found

Since acute sore throat is usually treated in general practice without bacteriological control, the differentiation of cases must be made on clinical grounds alone The decision to use penicillin then rests upon the latter My own routine is to treat all cases of tonsillitis, whether they exhibit follicular suppuration or not, with penicillin On the other hand the majority of cases of pharyngitis which I see are catarrhal in origin, although it is possible to distinguish a group with the stigmata of bacterial infection and these also I treat with penicillin

The régime of penicillin therapy described by Brumfitt and Slater was ineffective in eradicating the infecting organism in a proportion of cases I believe that in this particular condition oral penicillin in adequate doses is more effective than parenteral penicillin That penicillin has a more profound effect on the buccal flora when it is given by mouth than when it is given by injection, is evident from the fact that "black tongue" is a common complication of oral therapy but is rare with parenteral treatment The reason for this is not apparent but there may well be a similar difference in effect when treating throat infections with penicillin by the two routes The authors of this paper state that intramuscular penicillin is commonly used in practice for this complaint The vast majority of these cases are treated at home by general practitioners If the latter were asked, I am sure that it would be found that oral penicillin is far more commonly used in this condition than Brumfitt and Slater suppose Indeed the general practitioner is probably the only person who is in a position to give an authoritative opinion on this form of therapy, based upon personal experience

As Brumfitt and Slater say, the main object of antibacterial treatment in this condition is the prevention of those diseases believed to be due to streptococcal allergy Whether or not streptococci are being successfully eliminated from throats, there has been an enormous decline in the incidence of rheumatic fever since the dawning of the antibiotic era There would seem to be little reason to doubt that this is an example of cause and effect

Another very important object of antibacterial treatment of sore throats is the prevention of the more immediate complications due to spread of the infection Thus acute otitis media has been transformed in a decade from a surgical to a medical illness and mastoidectomy for acute mastoiditis has virtually disappeared These facts are surely again a tribute to the effectiveness of antibiotics in all these allied conditions

Therefore, Sir, I would conclude with a plea that no patient with a sore throat which might be expected on clinical grounds to respond to penicillin therapy should be denied the prophylactic and therapeutic benefits that such treatment confers Might I also suggest that information on this subject should be sought from those most intimately concerned with it—namely, the general practitioners

Twickenham, Middlesex DAVID WHEATLEY

SIR,—As a National Service medical officer spending his first year outside a hospital, I have been forcibly impressed by the problem confronting those who have to treat primary sore throat—an illness so common in everyday practice and so loudly proclaimed to be fraught with the possible sequelæ of rheumatic fever and acute nephritis, and yet so woefully neglected in the literature I was therefore greatly interested by certain points in the report by Captain Brumfitt and Captain Slater

1 As they remark, intramuscular penicillin, though less easily administered than the oral antibiotics and the cheap, but unfortunately "fading," sulphonamides, is the most effective drug in dealing with β hæmolytic streptococci

2 Sore throats due to streptococcal infection cannot be distinguished clinically from others, presumably due to viruses

3 In streptococcal sore throat penicillin neither shortens the clinical course of the disease appreciably, nor eradicates the organisms from the throat, unless given in adequate doses for 10 days The danger of rheumatic fever or acute nephritis is now really very small (Brumfitt and Slater suggest that it is probably less than 1% in endemic cases)

From all this it seems that, until some more effective chemotherapeutic agent is discovered, penicillin, sulphonamides, &c , can profitably be used only in severely toxic or septic cases of sore throat which have been shown bacteriologically to be streptococcal, and that, if penicillin is used, a full 10 day course should be given to reap the maximum benefit

Meanwhile nothing is to be gained by giving antibiotics or sulphonamides for any but these severe sore throats Such patients with less severe infections can be spared unnecessary and painful injections or tablet swallowing In fact we are back where we were 20 years ago, with formaldehyde lozenges, and, as my staff sergeant points out, iodine compound paint ("Mandl's paint"), as the mainstay of sore throat therapy

Royal Air Force,
Leconfield A R SMITH

PROLONGED PYREXIA IN CHILDREN POSSIBLY DUE TO INFLUENZA

SIR,—Pyrexia of unknown origin is common in children In some of them all investigations prove negative, no diagnosis is made and the pyrexia eventually subsides, as happened in 36% of the adult cases recorded by Reid[1]

Last January there was an epidemic of influenza in Northern Oxfordshire, and within two months, 32 of the 50 occupants of a home for physically handicapped children had bouts of pyrexia, many with pharyngitis and rhinitis and some with cervical adenitis In 24 the pyrexia lasted less than a week, but 3 had bouts of pyrexia lasting more than fourteen days without evidence of bacterial infection

CASE 1—A boy of 8 years complained of headache on Jan 20 His temperature was 101°F No abnormality was found in the chest, throat, nose, ears, or urine At the beginning of February he began to cough and had a slight cervical adenitis Nose and throat swabs grew only *Streptococcus viridans* He was given penicillin (500,000 units daily intramuscularly for five days) without any effect on the temperature He was allowed gradually to resume activity and on March 23, when he went home for Easter, his evening temperature was about 100°F Since his return he has been fit and well but with an occasional evening pyrexia, one night in three or four his temperature is 99–100°F

---

[1] Reid, J V O *Brit med J* 1956, ii 23

CASE 2.—A boy aged 7 years complained of headache on Jan. 17. His temperature was 102° F., he had rhinitis and pharyngitis but no other abnormal signs. By Jan. 19 his temperature was normal and his rhinitis and pharyngitis much improved. On Jan. 23 his temperature began to rise again, though at that time he had no symptoms and no physical signs save some rhinitis. Small lymph glands were palpable in the posterior triangle of the neck on Feb. 15, when culture of the nasal swab grew *Staphylococcus aureus* (resistant to penicillin but sensitive to aureomycin) and of the throat swab *Strep. viridans*, pneumococci, and neisseria. Aureomycin 250 mg. six hourly, was given for five days but the temperature chart remained the same. Further cultures on March 16 grew *Strep. viridans* and neisseria but no *Staph. aureus*, but his temperature was 100–100.8°F on most evenings until the Easter vacation. After he returned he still had an occasional evening pyrexia of 99–99.6°F.

CASE 3.—A boy aged 6 years had headache and pyrexia on Feb. 4. No abnormality was found in the chest, throat, ears, nose, or urine. By Feb. 15 there was some nasal catarrh and cough. No cervical or other lymph glands were palpable. Culture of a throat swab of March 12 grew only *Strep. viridans*. Penicillin (500,000 units intramuscularly daily) was given for five days, but the temperature remained unchanged until he went home on March 23. He returned fit and well but has an occasional evening temperature of 99–99.8°F.

In all these children X-ray films of the chest and Mantoux tests were negative, the urine was normal on at least two examinations, and the erythrocyte-sedimentation rate was 10–15 mm. in one hour. Glandular fever was excluded by blood examinations. An ear, nose, and throat surgeon said that he could find no active infection in any of them.

When it was apparent that these 3 children had an abnormal temperature with no obvious clinical cause, the temperature of every child in the home was repeatedly checked and found to be normal save in one boy who was apparently behaving like the 3 under discussion. He was older (13 years) and appeared well.

All these children had severe paralysis due to poliomyelitis. Perhaps children with extensive paralysis are especially prone to this type of pyrexia, though I have seen it in a physically normal child.

CASE 4.—In February, 1953, when 6 years of age, this boy developed a cough, laryngitis with some laryngeal spasm, a bronchial wheeze, and a pyrexia of 102°F. He was treated with trisulphonamide ('Sulphatriad'), the bronchial wheeze disappeared but the cough and pyrexia remained. X-ray films: chest normal, sinuses, some mucosal thickening of the right antrum. Urine normal. Nasal swab, *Staph. aureus*. Throat swab *Strep. viridans*. Mantoux 1 in 100 negative. Erythrocyte sedimentation rate 15 mm. in one hour. White blood cells 7000 per c.mm. with normal differential count. Brucella agglutinations negative on two occasions. Penicillin and chloramphenicol had no effect on the temperature.

After six months he was allowed to follow an unrestricted routine though the evening temperature was 99–100°F. At the end of nine months it was observed that he did not tire so easily and appeared to have much more energy. His temperature at this time was 97.6–98.2°F.

In general practice one is often told about pyrexia which proves to be non-existent, due to erroneous readings for temperature of children.[2] In the cases reported here, however, these were made by competent observers. As Ellis[3] says, special tests need not be done in every case of undiagnosed pyrexia unless the fever lasts for more than seven days or recurs soon after the initial attack. In the 4 cases described above no investigations were made until the illness had lasted a fortnight, by which time they had then recovered from their initial symptoms. Intensive blood examinations (e.g., for brucellosis) were not made, because the nature of the outbreak seemed to exclude such a diagnosis.

If the pyrexia of influenza lasts more than a week, the possibility of such complications as otitis media and patches of pulmonary consolidation has to be considered, though uncomplicated cases may last up to a month.[4] In the above patients, pyrexia lasted from four to nine months.

This prolonged pyrexia followed a non-bacterial upper-respiratory infection, and was probably due to the continued activity of a virus in the upper respiratory tract. Though the virus was not typed, all the patients were ill during a known influenza epidemic. According to Burnet,[5] influenza virus invades and multiplies in the cells lining the respiratory passages, and, with the possible exception of the conjunctival epithelium, in no other type of accessible human cells. The process continues, "sweeping over the epithelial surface like a prairie fire." The speed of spread determines the acuteness of the illness. Perhaps in the above patients the "prairie fire" was a slowly crawling smoulder, with neither complete destruction of the invading virus nor a state of symbiosis.

Chipping Norton, Oxon. F. E. JAMES.

A SPECIAL CAR SEAT

SIR,—When the user of a folding chair previously described[6] came to designing, he had some experience behind him. He had had ankylosing spondylitis for some years, and the seizing-up of both hips and the spine made it impossible for him to use the normal seat in a car.

Getting such handicapped persons out and about is of tremendous help to their well-being, and a special car seat was designed and built. There are three basic requirements: a back-rest reclining at about forty-five degrees; some sort of pivot or turntable on which the seat is mounted; and long runners so that the seat can be slid back and the user's feet can clear the front of the door gap.

First a plywood box was made reinforced inside with a 2 × 2 in. wooden frame. To this were screwed two brackets of $^1/_{16}$ in. sheet steel to support the back-rest (see figure). The back-rest is an oak frame shaped like an inverted U and strung with camp chair canvas. The frame is bolted at its bottom ends into the 2 × 2 in. side-members, and some 12 in. above the bolts it is secured by a horizontal traverse rod passing through a length of hollow brass curtain-rail ($^1/_4$ in.). The rod is threaded at both ends and "clewed up" by wing nuts; it also provides the lower anchorage for the canvas.

The seat cushion is internally sprung and is comfortable even for long journeys. If the user wanted to replace it by one of foam rubber, the seat box would have to be altered to give the extra support to the flat area of rubber. The chair has been made so stout, however, that, though eight years old it shows no sign of falling to pieces and needing replacement. The head rest is a bit of three-ply wood some 6 × 10 in. which passes through a slot in the back of the frame, made of bent hoop iron. Padding for the back rest is provided by a normal sized pillow covered with chintz.

Before this chair was built a suitable car had to be found. It had to have a door gap at least 3 feet wide and unlimited height for easy access The height is needed when the disabled person has only one helper, otherwise a second helper, inside the car, has to take most of his weight and duck him under the roof beam Thus the choice fell on a coupé convertible When there is only one helper, the hood is opened to the halfway stage and the disabled person is lowered on to the seat This is then revolved on its turntable until it faces forward Getting him out is much simpler, for lifting a person towards one is easier than supporting his weight while moving him away from one

Obituary

CHARLES-EDWARD AMORY WINSLOW

B S, A M, Dr P H

Dr Winslow, professor emeritus of public health at Yale University, died on Jan 8 at the age of 79

He was born at Boston and he took the degree of bachelor of science at the Massachusetts Institute of Technology in 1898 For some years he was assistant health officer at Montclair, New Jersey, and he worked during the summers in the engineer's office of the Massachusetts board of health In 1902 he was appointed instructor in sanitary bacteriology at the Massachusetts Institute of Technology and in 1905 he was promoted to assistant professor In 1910 he became associate professor of biology at the College of the City of New York and curator of public health in the American Museum of Natural History In 1915 he was appointed to the chair at Yale which he held until he retired in 1945 He was editor-in-chief of the *American Journal of Bacteriology* from 1916 to 1944 In 1942 he received the Sedgwick medal of the American Public Health Association After the late war he continued his earlier work for the health section of the League of Nations in the counsels of the World Health Organisation, and his monograph on W H O's immense task, *The Cost of Sickness and the Price of Health* (1951), was one of the last of his widely ranging publications on public health In 1953 he received the Lasker award

One of his medical colleagues in this country writes

Winslow was a commanding figure, yet he never seemed remote, in spite of his noble and somewhat aristocratic appearance In many ways one thinks of him as the ideal teacher—eloquent, scholarly, and humane He taught men and women of all ages and degrees of experience, at all levels from the World Health Assembly to the smallest classroom, without ever laying down the law He was one of us In his teaching there was none more infectiously enthusiastic there was none less rabid

He pursued his subject—the health of the people—with a devotion that was passionate in its intensity Yet he never lost touch with reality, and most of his public health ideals were severely practical Indeed, it is characteristic of him that, in contrast with an outward philosophic calm, his powerful mind was directed mainly to environmental hygiene The healthy housing of the people was his chief task, and he spent endless time and effort in working out the principles and demonstrating the practice In many respects he followed the lead of the English pioneers of public health and introduced the best of their work to the United States in the tradition of men like Shattuck and Hermann Biggs, but he went further, by instituting target standards in housing and environmental work, and he was tireless in showing how they could be achieved They are still a shining example to the world

The establishment of standards was one of his notable contributions to health and education, and their application to schools of public health has had a widespread influence on their teaching methods as well as on their range of subjects

Winslow was a beneficent influence on his time and generation, and his work and his gracious personality will be remembered in the annals of preventive medicine "Every noble life leaves the fibre of itself interwoven for ever in the work of the world"

Notes and News

INTRA-ARTERIAL PENICILLIN

IN some Russian experiments[1] penicillin with a radioactive marker (^{35}S) was injected into rabbits, and its concentration in various tissues was estimated 45 minutes and 2½ hours later Injections were made into an ear vein, into the muscle of the right shoulder, and into the main artery of the right leg, and the concentration of penicillin was estimated in the plasma and in the muscles of the right and left leg Both normal animals and animals with an artificial abscess in the right leg were used In the normal animal it was found that after intravenous or intramuscular injection, the concentration of penicillin was greater in the plasma but equal in the muscles of the two legs, whereas after intra arterial injection the concentration was much greater in the muscles of the leg into whose artery the penicillin had been injected In animals with an artificial abscess, the concentration of penicillin was greater in the muscles surrounding the abscess than it was in normal muscles, and this difference was greater when the penicillin had been injected into the corresponding artery

From these observations it was deduced that, in the treatment of infection of a limb, intra arterial injection is the method of choice 536 such injections were given to 110 patients using 20 ml of 0 5% procaine solution containing 100,000 units of penicillin The results were excellent in all acute infections, but in chronic osteomyelitis such injections did not prevent exacerbations In chronic trophic ulcers the results were good but not outstandingly better than with other methods of treatment The investigators conclude that injection into the main artery of the affected limb is the most effective means of ensuring high concentration of penicillin at the site of infection

STREPTOCOCCAL INFECTIONS

IN a paper read to the section of pathology of the Manchester Medical Society on Dec 12, Dr R E O Williams said that the first and most striking feature in the epidemiology of streptococcal infections was the great decline in mortality from the most characteristic streptococcal disease—scarlet fever The incidence of streptococcal infection seemed to have declined much more slowly than mortality, and even now one could estimate that about 20% of children had a streptococcal sore throat each year The fact that streptococcal infections were sometimes followed by rheumatic fever was perhaps the chief reason for continuing interest in them, the proportion complicated by rheumatic fever was very difficult to discover, but it was almost certainly far less in the civilian population than the 3% observed in the U S Armed Forces

Studies of healthy children for carriage of streptococci showed that those who had had their tonsils removed were less often carriers than those who retained their tonsils In the experience of Dr Williams and his colleagues there had also been some indication that those without their tonsils were slightly less likely to become infected (or ill) when exposed to an epidemic of streptococcal infection There was no convincing evidence that they were less liable to non streptococcal illness

The way in which infection spread in a limited community confirmed the great importance of the nasal carrier in the dissemination of streptococci In the control of streptococcal infections the nasal carrier was the most important person to isolate and treat Convalescents from the acute illness, unless adequately treated, could form an important pool of chronic carriers Chemoprophylaxis might be a valuable method of preventing streptococcal infections in particularly vulnerable persons, particularly convalescents from rheumatic fever, and in some circumstances for controlling the spread of epidemics in limited communities

FILM-STRIP ON INTRAMUSCULAR INJECTION

The Technique of Intramuscular Injection is a film strip (24 frames, colour) designed for teaching student nurses A commentary, printed in bold type, that can be easily read by the tutor in subdued lighting is supplied with it, and a long playing gramophone record of the narration read by a professional commentator is also available

The reasons for using intramuscular rather than subcutaneous injections are explained with the aid of a chart Misplaced parenteral iron causes both unsightly stains and delayed absorption, it is therefore particularly important that the technique is correct when injecting the sponsors' intramuscular iron preparation The site of the injection is discussed and the method demonstrated in detail Finally the siteing of subsequent injections in a series is mentioned

---

[1] *Chirurgia* 1956, 7, 41

This is an extremely useful audio visual aid for training student nurses Good use is made of diagrams and a chart to illustrate the points made in the commentary, though it is unfortunate that an anatomical diagram showing the structures to be avoided in the right buttock is followed by a demonstration of the positioning and injection in the left buttock It would have been advisable, also to leave out the suggestion that certain precautions may be omitted if the nurse is in a hurry

Copies of the film strip are available from Benger Laboratories Ltd, Holmes Chapel, Cheshire

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Jan 7, with Prof Stanley Alstead, the president, in the chair, N K Barber and G C Robin were admitted fellows of faculty

Food Standards Committee

The Minister of Agriculture, Fisheries and Food has appointed Prof B S Platt a member of this committee in place of Prof S J Cowell who has retired

Royal Medico-Psychological Association

Child Psychiatry Section—A meeting of this section is to be held on Thursday, Feb 14, at 5 30 P M at 11, Chandos Street, London, W 1, when there will be a discussion on psychological factors in the production of epilepsy All pediatricians are invited to attend

British Supporting Group for the World Medical Association

A meeting to inaugurate this group is to be held at B M A House, London, W C 1, on Tuesday, Jan 29, at 3 30 P M Dr Alexander Hall, the president of the British Medical Association, will take the chair and Dr S Wand and Dr J A Pridham will speak

Australasian Research Fellowship

The Royal Australasian College of Physicians has instituted the Adolph Basser fellowship (£A3750 p a) for research in any branch of science associated with internal medicine The research must be done in Australia or New Zealand Further particulars may be had from the hon secretary of the college, 145, Macquarie Street, Sydney The closing date for applications is March 15

Fellowships in Clinical Research

The Medical Research Council invite applications for fellowships tenable at centres in the United Kingdom during 1957–58 from medical graduates who wish to prepare themselves for a career in clinical research

The awards will be made for one year in the first instance and will be renewable annually to a maximum of three years in all Stipend will be at the rate of £950–£75–£1100 per annum with superannuation Applications must be sponsored by the head of the appropriate department in the candidate's university or medical school and an undertaking will be required that a suitable academic post in a clinical department will be available to the candidate in that institution on satisfactory completion of the period of study under the fellowship Forms of application may be had from the secretary of the council 38 Old Queen Street London S W 1 to whom they must be returned not later than March 1 1957 and unlimited height for easy access The height is needed when the disabled person has only one helper, otherwise a second helper, inside the car, has to take most of his weight and duck him under the roof beam Thus the choice fell on a coupe convertible When there is only one helper, the hood is opened to the halfway stage and the disabled person is lowered on to the seat This is then revolved on its turntable until it faces forward Getting him out is much simpler, for lifting a person towards one is easier than supporting his weight while moving him away from one

Stocksfield,
Northumberland E H TREWEEKS

Obituary

CHARLES-EDWARD AMORY WINSLOW

B S , A M , Dr P H

Dr Winslow, professor emeritus of public health at Yale University, died on Jan 8 at the age of 79

He was born at Boston and he took the degree of bachelor of science at the Massachusetts Institute of Technology in 1898 For some years he was assistant health officer at Montclair, New Jersey, and he worked during the summers in the engineer's office of the Massachusetts board of health In 1902 he was appointed instructor in sanitary bacteriology at the Massachusetts Institute of Technology and in 1905 he was promoted to assistant professor In 1910 he became associate professor of biology at the College of the City of New York and curator of public health in the American Museum of Natural History In 1915 he was appointed to the chair at Yale which he held until he retired in 1945 He was editor-in-chief of the *American Journal of Bacteriology* from 1916 to 1944 In 1942 he received the Sedgwick medal of the American Public Health Association After the late war he continued his earlier work for the health section of the League of Nations in the counsels of the World Health Organisation, and his monograph on W H O 's immense task, *The Cost of Sickness and the Price of Health* (1951), was one of the last of his widely ranging publications on public health In 1953 he received the Lasker award

One of his medical colleagues in this country writes

Winslow was a commanding figure, yet he never seemed remote, in spite of his noble and somewhat aristocratic appearance In many ways one thinks of him as the ideal teacher—eloquent, scholarly, and humane He taught men and women of all ages and degrees of experience, at all levels from the World Health Assembly to the smallest classroom, without ever laying down the law He was one of us In his teaching there was none more infectiously enthusiastic there was none less rabid

He pursued his subject—the health of the people—with a devotion that was passionate in its intensity Yet he never lost touch with reality, and most of his public health ideals were severely practical Indeed, it is characteristic of him that, in contrast with an outward philosophic calm, his powerful mind was directed mainly to environmental hygiene The healthy housing of the people was his chief task, and he spent endless time and effort in working out the principles and demonstrating the practice In many respects he followed the lead of the English pioneers of public health and introduced the best of their work to the United States in the tradition of men like Shattuck and Hermann Biggs, but he went further, by instituting target standards in housing and environmental work, and he was tireless in showing how they could be achieved They are still a shining example to the world

The establishment of standards was one of his notable contributions to health and education, and their application to schools of public health has had a widespread influence on their teaching methods as well as on their range of subjects

Winslow was a beneficent influence on his time and generation, and his work and his gracious personality will be remembered in the annals of preventive medicine " Every noble life leaves the fibre of itself interwoven for ever in the work of the world "

Notes and News

INTRA-ARTERIAL PENICILLIN

IN some Russian experiments [1] penicillin with a radioactive marker (^{35}S) was injected into rabbits, and its concentration in various tissues was estimated 45 minutes and 2½ hours later Injections were made into an ear vein, into the muscles of the right shoulder, and into the main artery of the right leg, and the concentration of penicillin was estimated in the plasma and in the muscles of the right and left leg Both normal animals and animals with an artificial abscess in the right leg were used In the normal animal it was found that after intravenous or intramuscular injection, the concentration of penicillin was greater in the plasma but equal in the muscles of the two legs, whereas after intra arterial injection the concentration was much greater in the muscles of the leg into whose artery the penicillin had been injected In animals with an artificial abscess, the concentration of penicillin was greater in the muscles surrounding the abscess than it was in normal muscles, and this difference was greater when the penicillin had been injected into the corresponding artery

From these observations it was deduced that, in the treatment of infection of a limb, intra arterial injection is the method of choice 536 such injections were given to 116 patients using 20 ml of 0 5% procaine solution containing 100,000 units of penicillin The results were excellent in all acute infections, but in chronic osteomyelitis such injections did not prevent exacerbations In chronic trophic ulcers the results were good but not outstandingly better than with other methods of treatment The investigators conclude that injection into the main artery of the affected limb is the most effective means of ensuring high concentration of penicillin at the site of infection

STREPTOCOCCAL INFECTIONS

IN a paper read to the section of pathology of the Manchester Medical Society on Dec 12, Dr R E O Williams said that the first and most striking feature in the epidemiology of streptococcal infections was the great decline in mortality from the most characteristic streptococcal disease—scarlet fever The incidence of streptococcal infection seemed to have declined much more slowly than mortality, and even now one could estimate that about 20% of children had a streptococcal sore throat each year The fact that streptococcal infections were sometimes followed by rheumatic fever was perhaps the chief reason for continuing interest in them, the proportion complicated by rheumatic fever was very difficult to discover, but it was almost certainly far less in the civilian population than the 3% observed in the U S Armed Forces

Studies of healthy children for carriage of streptococci showed that those who had had their tonsils removed were less often carriers than those who retained their tonsils In the experience of Dr Williams and his colleagues there had also been some indication that those without their tonsils were slightly less likely to become infected (or ill) when exposed to an epidemic of streptococcal infection There was no convincing evidence that they were less liable to non streptococcal illness

The way in which infection spread in a limited community confirmed the great importance of the nasal carrier in the dissemination of streptococci In the control of streptococcal infections the nasal carrier was the most important person to isolate and treat Convalescents from the acute illness, unless adequately treated, could form an important pool of chronic carriers Chemoprophylaxis might be a valuable method of preventing streptococcal infections in particularly vulnerable persons, particularly convalescents from rheumatic fever, and in some circumstances for controlling the spread of epidemics in limited communities

FILM-STRIP ON INTRAMUSCULAR INJECTION

The Technique of Intramuscular Injection is a film strip (24 frames, colour) designed for teaching student nurses A commentary, printed in bold type, that can be easily read by the tutor in subdued lighting is supplied with it, and a long playing gramophone record of the narration read by a professional commentator is also available

The reasons for using intramuscular rather than subcutaneous injections are explained with the aid of a chart Misplaced parenteral iron causes both unsightly stains and delayed absorption It is therefore particularly important that the technique is correct when injecting the sponsors' intramuscular iron preparation The site of the injection is discussed and the method demonstrated in detail Finally the siting of subsequent injections in a series is mentioned

---

[1] *Chirurgia* 1956 7, 41

This is an extremely useful audio visual aid for training student nurses Good use is made of diagrams and a chart to illustrate the points made in the commentary though it is unfortunate that an anatomical diagram showing the structures to be avoided in the right buttock is followed by a demonstration of the positioning and injection in the left buttock It would have been advisable also to leave out the suggestion that certain precautions may be omitted if the nurse is in a hurry

Copies of the film-strip are available from Benger Laboratories Ltd, Holmes Chapel, Cheshire

University of Cambridge

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Jan 7, with Prof Stanley Alstead, the president, in the chair, N K Barber and G C Robin were admitted fellows of faculty

Food Standards Committee

The Minister of Agriculture, Fisheries and Food has appointed Prof B S Platt a member of this committee in place of Prof S J Cowell who has retired

Royal Medico-Psychological Association

Child Psychiatry Section—A meeting of this section is to be held on Thursday, Feb 14, at 5 30 P M at 11, Chandos Street, London W 1, when there will be a discussion on psychological factors in the production of epilepsy All pediatricians are invited to attend

British Supporting Group for the World Medical Association

A meeting to inaugurate this group is to be held at B M A House, London, W C 1, on Tuesday, Jan 29, at 3 30 P M Dr Alexander Hall, the president of the British Medical Association, will take the chair and Dr S Wand and Dr J A Pridham will speak

Australasian Research Fellowship

The Royal Australasian College of Physicians has instituted the Adolph Basser fellowship (£A3750 p a) for research in any branch of science associated with internal medicine The research must be done in Australia or New Zealand Further particulars may be had from the hon secretary of the college, 145, Macquarie Street, Sydney The closing date for applications is March 15

Fellowships in Clinical Research

The Medical Research Council invite applications for fellowships tenable at centres in the United Kingdom during 1957–58 from medical graduates who wish to prepare themselves for a career in clinical research

The awards will be made for one year in the first instance and will be renewable annually to a maximum of three years in all Stipend will be at the rate of £950–£75–£1100 per annum with superannuation Applications must be sponsored by the head of the appropriate department in the candidate's university or medical school and an undertaking will be required that a suitable academic post in a clinical department will be available to the candidate in that institution on satisfactory completion of the period of study under the fellowship Forms of application may be had from the secretary of the council 38, Old Queen Street London S W 1 to whom they must be returned not later than March 1 1957

Hungarian Interpreter Telephone Service

In the coming weeks doctors who are asked to attend Hungarian refugees may find themselves in need of an interpreter's help The W V S (Women's Voluntary Services) ask us to say that one of their interpreters will be available by phone from 10 A M to 6 P M on weekdays and 10 A M to 12 30 P M on Saturdays at WHItehall 7383, ext 11, and from 10 A M to 6 P M on Sundays at WEStern 2053

Marlborough Day Hospital, London

On Monday, Feb 4 at 8 15 P M, at this hospital, 38, Marlborough Place, N W 8, Dr T F Main will speak on the Past and the Present in Neurosis

Chartered Society of "Queen Square"

This society will shortly hold an election for pensions (£20 p a each) for needy people with incurable nervous diseases Further particulars may be had from the society, Queen Square House, Queen Square, London, W C 1

Albania and Bulgaria Rejoin W H O

The People's Republics of Albania and Bulgaria have *informed Dr M G Candau, director-general of the World* Health Organisation, of the decision of their governments to resume active participation in the organisation

Cerebral Palsy in Mentally Retarded Children

A meeting on this subject will be held at the Fountain Hospital, Tooting Grove, London, S W 17, on Thursday, Jan 24 at 5 30 P M. Dr F A Elliott will be in the chair and Dr K Bobath and Dr John Foley will speak

Society for Applied Bacteriology

The programme for the conference which this society is holding in Leeds from July 2 to 5, will include an international symposium on the formation and germination of bacterial spores Further details of the meeting can be had from the secretary, G Sykes, Boots Pure Drug Co Ltd, Microbiology Division, Nottingham

Courses for General Practitioners at Liverpool

The following courses for general practitioners are to be held this year March 6–27 (obstetrics), March 31–April 28 (general), May 5–26 (general), May 20–24 (anæsthetics), June 2–23 (general), July 3–24 (eyes and E N T) Further particulars may be had from the dean of the faculty of medicine, The University, Liverpool, 3

Sir Gordon Gordon Taylor has been elected an honorary fellow of the Medical Society of London

ADDENDUM *Neurone Selection in the Relief of Pain* —Dr R M Maher asks us to say that for the pathological findings recorded in his article of Jan 5 he is indebted to Dr J A Shrigley, lately pathologist at the Christie Hospital, Manchester t least all which is obvious to the naked eye, is removed, nd that the remnants are secretory—to be stimulated, if ecessary, by the thyrotropic hormone of the pituitary

In operating on nodular goitres it is often found that he upper poles have escaped the nodular process and onsist of soft homogeneous secreting thyroid tissue In hese cases, particularly when toxicity is minimal or bsent, we never hesitate to leave behind the upper poles

This technique has been in use for some years, and it is urprising that patients in whom only very small remants of the selected tissue had been preserved continue o be perfectly euthyroid One can fairly assume that, rovided that a little normal or nearly normal tissue emains, the pituitary gland will stimulate it to produce sufficient amount of thyroid hormone for the patient Fig 5 schematically presents the essential steps in this technique)

Adequate Operation

Adequate operation is a sine qua non in preventing recurrence

In operating on a diffuse toxic goitre about 1–4 g of the posterolateral margin is left on either side In gauging the remnants account is taken of the size of the gland, the original degree of toxicity, the reaction of the gland to the anti thyroid drug, the patient's personality, and the presence of any cardiovascular involvement

In operations on the nodular variety the quality of the remnants—i e, removal of all nodular tissue—is the primary concern, the amount of gland to be left is determined by the patient's toxic state

In cases with lymphadenoid change it must be borne in mind that myxœdema is an almost inevitable sequel (Greene 1950, 1953) irrespective of the size of the remnants In such cases operation—e g, for the relief of pressure symptoms—has merely anticipated the natural course of the condition

Reconstitution

The operation is so designed that the remnants are reconstituted in such a manner as to resemble small lateral lobes With this in view, when the lobe has been delivered and the line of section decided on, the gland is sectioned in an oblique manner, so that the remnant can be folded over and medially and, with a few fixing or anchoring sutures, can be made to nestle snugly against the lateral aspect of the trachea (fig 6) Quite apart from the surgical neatness effected, this is also a hæmostatic procedure and ensures that the remnant is covered by its capsule, which cuts down oozing and the subsequent production of serum We believe also that this procedure does in a small but positive way prevent recurrences the growth of the remnant being limited by its capsule, and that in some cases, it does away with the necessity of draining the operation site

Summary

At the New End thyroid clinic and department of endocrinology cases of true recurrent goitre amounted to about two fifths of the number of cases referred as recurrent goitre

The commonest cause of recurrence is probably an inadequate initial operation Most "recurrences" therefore are in fact continued growths of pathological tissue which remained after the first operation Factors promoting recurrence are failure to ligate the inferior thyroid arteries and to remove the pyramidal lobe

We wish to thank Staff Nurse S M Torkington for figs 5 and 6 Miss E Mason for the photographs and figs 2 and 3 and Mrs M J Lange for help with statistics

THE MIDDLESEX HOSPITAL

Tetraethyl lead, $(C_2H_5)_4Pb$ (T E L), a highly toxic liquid, is manufactured on a large scale, distributed throughout the world, and blended with many types of petrol, yet poisoning is rare because of the stringent precautions taken in its manufacture and handling Recent cases have arisen sporadically in men cleaning tanks which have contained leaded petrol Such incidents have been reported in the United Kingdom by Cassells and Dodds (1946) and Walker and Boyd (1952), in the U S A by Kitzmiller et al (1954), and in Germany by Fischer (1950) and Muller (1953)

This organo-metal compound is absorbed through the skin and the respiratory and alimentary mucosæ, it is probably distributed in a non-ionic form and being lipoid-soluble, is concentrated in the brain, body fat and liver (Kehoe and Thamann 1931) Its toxicity is due to its lead content (Kehoe 1927) and because of selective uptake manifestations of poisoning are dominated by involvement of the central nervous system and differ from those of inorganic lead poisoning where the initial lead distribution is different Although the inhalation of T E L vapour for a brief period may be fatal the continued excretion of large amounts of lead in the urine for some time after the removal of symptomless workers from prolonged minor exposure, suggests that appreciable quantities of T E L may be absorbed and the lead stored in a relatively non-toxic form

The clinical picture has been described in detail by Machle (1935) and Kehoe (1925) Mild intoxication causes headache, irritability, restlessness, anxiety, fatigue, insomnia with bad dreams and minor gastrointestinal symptoms, including anorexia, vomiting and diarrhœa There is sometimes a persistent metallic taste These symptoms may easily be mistaken for those of an anxiety state In more severe intoxication there is a similar "prodromal" stage lasting a week or more, followed by a toxic psychosis, the pattern of which depends on the patient's underlying personality and is remarkably variable from individual to individual and sometimes from day to day Hallucinations, delusions and intense fear are usual and suicidal attempts not infrequent Coma and convulsions occur in the most severe cases Physical signs are few the most important being tremor, increased tendon reflexes, hypothermia bradycardia hypotension and loss of weight The classical signs of inorganic lead poisoning are not found Relapses are common, but chronic effects and permanent sequelæ have not been reported The diagnosis is confirmed by estimations of the urinary lead excretion but blood-lead levels are seldom much increased

Small hæmorrhages may be found in the meninges brain and the gastro intestinal tract, but there are no characteristic necropsy findings

Three moderately severe cases are described in this report and the effect on lead excretion of edathamil calcium disodium (edathamil $CaNa_2$, 'Versene'), given intravenously and orally, and of penicillamine given orally are compared A fourth case with a severe psychosis is mentioned, but the severity of the illness prevented detailed biochemical observation

The Outbreak

In March and April, 1956, a team of five men worked for 6 weeks cleaning underground tanks which had contained leaded petrol Four men (cases 1–4) who worked in the tanks were admitted to hospital suffering from tetraethyl lead poisoning The fifth man, who remained on the surface, showed neither clinical nor biochemical evidence of poisoning

The affected men scraped the deposit containing tetra ethyl lead from the floors and sides of the tank, and shovelled it into buckets, which were hauled to the surface and emptied into pits They were provided with protective clothing and equipment designed to protect against fluid and vapour, consisting of oilskin suits and hats, rubber boots and gloves, and a face mask with a positive pressure air-line For various reasons they neglected the strict precautions laid down for this type of work

The following investigations were performed in cases 1–3 on admission

Hæmoglobin and red cell count, examination of red cells for stippling, total and differential white count Liver function tests, including cephalin cholesterol and zinc sulphate flocculation, and thymol turbidity tests, estimation of serum albumin and globulin, electrophoresis of serum proteins, estimation of prothrombin content, and serum bilirubin Blood-urea Urine deposit and routine estimation for protein, reducing substances and excess urobilinogen Electro encephalogram Chest X rays and films of the upper abdomen for assessment of the density of the liver shadow In every case the results of these tests were normal

During the period in hospital urine was collected daily for estimation of lead, coproporphyrin and creatinine In addition lead analysis was performed on daily fæcal samples and on blood samples taken frequently

The urine and fæces were passed directly into lead free glass bottles and were collected over 24 hour periods Blood (20 ml clotted) was collected into special all glass syringes and when edathamil $CaNa_2$ was given intravenously the sample was taken immediately before the infusion The lead concentrations in urine, fæces and blood were estimated by modifications of the methods of Bambach and Burkey (1942) which give the following approximate values for non exposed men urine 50–100 µg daily, fæces 20–400 µg daily, and blood 10–60 µg per 100 g Coproporphyrin III was extracted from urine samples by a method based on that of Schwartz et al (1951) and then determined spectrophotometrically in a manner similar to that described by Rimington and Sveinsson (1950) (Normal = about 0–50 µg daily) Urinary creatinine was estimated by the Jaffe reaction

In cases 1–3 the men were treated in turn for 3 day periods with edathamil $CaNa_2$, 1 g per 30 lb body-weight per day by intravenous infusion, lasting 4–6 hours, with penicillamine 300 mg t d s by mouth and with edathamil $CaNa_2$ 1 g q i d by mouth In each case treatment was preceded by 2 control days during which urine, fæces and blood were collected for analysis and intervals of several days were allowed between the different forms of treatment

The men were confined to bed for the first few days and sedated as necessary with amylobarbitone in doses from gr $^3/_4$ t d s to gr 3 b d, with gr 3–6 at night A high fluid intake and full diet were encouraged throughout

After discharge from hospital the men were examined and further analyses were made weekly Edathamil $CaNa_2$ 1 g q i d was given by mouth for alternate weeks until their clinical condition was satisfactory and the basal lead excretion normal They then started work *of a different kind involving no exposure to toxic hazards*

Case-reports

Case 1 —A man aged 41 had cleaned tanks, including a few which had contained leaded petrol, regularly for 10 years and was foreman of the team He had never previously noted any ill effects

His first symptom, dryness of the throat, appeared 3 weeks after starting work and was followed by cramps in the legs, anorexia, occasional vomiting, *loss of a few pounds'* weight, difficulty in falling asleep, tremor of the hands and intense anxiety about his own condition and that of the other men for whom he was responsible On a sudden impulse he travelled 150 miles by taxi to see whether his workmates were also ill Before admission he had been treated with small doses of phenobarbitone without effect

On admission on May 1, 1956, he was intensely anxious, he appeared tired but required large doses of amylobarbitone to induce sleep Weight 165 lb (74 8 kg), temperature 98 4°F (36 9°C), pulse 70 per min, blood pressure (B P) 125/70 mm Hg There was a fine tremor of the outstretched hands, but no other physical signs of disease

Subjective improvement was apparent once he had been reassured about the condition of his workmates but he continued to show mood swings, apparently unrelated to treatment The B P stabilised at 110/60

He was discharged home after 20 days, weight 162 lb (73 5 kg), subjectively much improved but still complaining of a dry throat and occasional pains in the limbs Further improvement seemed to coincide with the oral administration *of edathamil $CaNa_2$ and he was symptom free and returned* to work 11 weeks after the onset of his illness

Case 2 —A man aged 28 had worked in tanks only on this one occasion After a month he complained of difficulty in falling asleep, nightmares, anorexia, a persistent metallic taste, intermittent diarrhœa and vomiting, *retro orbital* headaches and giddiness He had had occasional upper abdominal pain and vomiting for the previous 2 years but had otherwise been fit

When first seen on April 30, he claimed to have lost 20 lb (9 1 kg) *during the previous* 6 weeks He was anxious but not excited and he had no tremor His weight was 162 lb (73 5 kg), B P 110/75 As his symptoms persisted, he was admitted to hospital on May 9, when he weighed 161 lb (73 0 kg), temperature 98 2°F (36 8°C), pulse 60 B P 120/75 A barium meal examination showed nothing abnormal and the fæces were persistently negative for occult blood

Throughout his stay in hospital he was alternately elated and depressed and suffered from occasional attacks of upper abdominal discomfort, vomiting and diarrhœa, apparently unrelated to treatment His B P stabilised at 100/60 He was discharged home on June 2, but readmitted 2 days later because of further vomiting which rapidly subsided with antacids and a bland diet He was finally discharged on June 9, weighing 158 lb (71 7 kg)

Between June 9 and July 30 he was given two 7 day courses *of oral edathamil $CaNa_2$ He abandoned the first after 4 days* because of abdominal pain and diarrhœa The second course was uneventful At this time his B P was 115/70 and his weight had risen to 170 lb (77 1 kg) Apart from occasional headache he was symptom free on July 30 when he started work after 11 weeks' illness

Case 3 —A man aged 25 had also worked inside tanks for only 6 weeks When seen on April 30 he complained only of insomnia but by May 10 he looked pale and thinner and complained of irritability, impairment of concentration, loss of libido, headache, occasional auditory hallucinations, anorexia, nausea, abdominal discomfort, vomiting and loss of a few pounds' weight

On admission on May 17, he appeared anxious His weight was 146 lb (66 2 kg), temperature 97 8°F (36 5°C), pulse 64 B P 95/65 Improvement was gradual and initially seemed unrelated to treatment He was worried most *by his memory* defect Formal testing showed an average intelligence and suggested a good prognosis for recovery, which was subsequently justified He was discharged home on June 3, weighing 148 lb (67 1 kg), and was given three 7 day courses of oral *edathamil $CaNa_2$ during which* he said he felt particularly well He was symptom free and began work on July 10, when his B P was 110/55 and his weight had risen to 150 lb (68 0 kg)

Case 4 —A man aged 31 had worked intermittently in leaded petrol tanks for about a year When first seen on April 30 he *strongly denied any symptoms* but his blood pressure was 95/70 and he had a slight tremor of the hand He was known to have been a heavy drinker and to have suffered violent mood swings in the past

He was admitted to hospital on May 7 complaining of dizziness, confusion, and insomnia and was said to have lost consciousness for a few minutes some days previously He was restless and resisted examination His B P was 90/60 and weight 140 lb (63 5 kg) Amylobarbitone gr 3–6 seemed to aggravate his restlessness and within two days he was deluded, visually and aurally hallucinated and violent

He was transferred to a mental hospital on May 14 During the next few days he was frequently violent and appeared intermittently anxious, confused and paranoid Drug treatment was impossible and deterioration was progressive On May 25 he was given unmodified electroconvulsion treatment (E C T) and immediately became quiet and coöperative and for the first time had an adequate intake of food and fluids B P was 85/55 immediately after this treatment He slept well Edathamil CaNa$_2$ was given intravenously on the next 2 days but on the 3rd day he again became restless and was given a second treatment with E C T , after which he remained lucid and rational He was given infusions of edathamil CaNa$_2$ on the next 3 days with further improvement

He was discharged from hospital on June 5 and was given three courses of oral edathamil CaNa$_2$ on alternate weeks at the end of which his daily urine lead excretion was within normal limits At this time (July 23) his B.P had risen to 110/70 and his weight to 150 lb (68 0 kg) He was, however, still showing signs of a mild depression as well as certain paranoid traits and was therefore given six further treatments of E C T between Aug 15 and Sept 18 with the object of preventing these forming any ingrained pattern of conduct

After this he improved rapidly and he resumed light work on Oct 9 His illness lasted about 6 months

Effects of Treatment

Table I shows that, though the urinary and fæcal lead excretion before treatment was greater than normal, the ratio between the two was about the same as in non-exposed persons excreting normal amounts of lead The variation in lead excretion before treatment is to be expected, as many factors influence lead output Creatinine estimations confirmed the accuracy of the urine collection (Note In correlating urinary and fæcal lead excretion for a 24-hour period, the urine figures for that period were allied to the fæcal figures for the following period)

TABLE II—DAILY EXCRETION OF LEAD IN µG

Case	Urine	Fæces	Total
1	557	170	727
2	99	100	199
3	391	250	641
4	133	190	323

Of the three cases studied fully, the highest lead excretion was found in the man (case 1) who had been exposed to tetraethyl lead the longest, but had not previously suffered from symptoms of poisoning Before treatment his mean daily excretion was 1688 µg (urine 688 µg , fæces 1000 µg) compared with 810 µg (urine 270 µg , fæces 540 µg) in case 2, and 932 µg (urine 222 µg , fæces 710 µg) *in case 3, in both of which the symptoms* were no less severe Data on case 4 are scanty because of the nature and severity of the illness in this case but the mean daily excretion before treatment was 5123 µg. (urine 789 µg , fæces 4334 µg)

In case 1, lead excretion continued at a relatively greater rate than in the others, during and between the periods of treatment, and by July 9, about 2 months after treatment was first started and immediately following a week's course of oral edathamil CaNa$_2$, the excretion in each case had fallen as shown in table II

This suggests that in case 1 a large amount of tetraethyl lead had been absorbed over a long period (he had been exposed to it intermittently for 10 years) and that much of the lead had been stored in a relatively non-toxic form whereas in case 4 a smaller amount of tetraethyl lead had been absorbed over a short period (he was exposed to it for only 6 weeks), but he suffered severe poisoning because the rate of absorption much exceeded that of degradation and excretion

The greater excretion of lead on the first day compared with the subsequent days of the periods between treatments was presumably due to a residual effect of the drugs and this also explains why the lead excretion was greater in these periods than before treatment

Table III and figs 1 and 2 show that intravenous edathamil CaNa$_2$ (1 g per 30 lb body-weight) increased the urinary lead excretion sevenfold and the total excretion threefold, whilst oral edathamil CaNa$_2$ and

TABLE III—EXCRETION OF LEAD AFTER TREATMENT, EXPRESSED AS PERCENTAGE OF PRE TREATMENT FIGURE

Treatment	Case	Urine	Fæces	Total

	Mean	452		

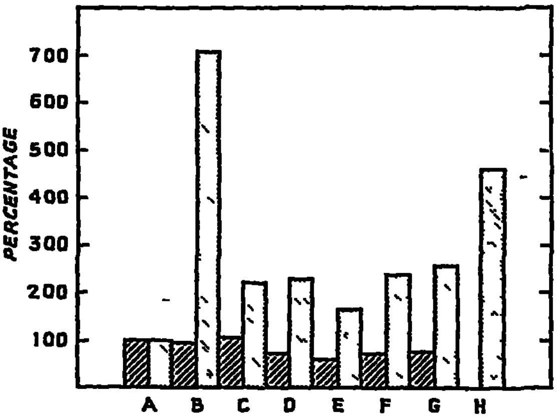

Fig 1—Total mean excretion of lead in cases 1, 2, and 3 after treatment, expressed as percentage of total mean excretion before treatment. Stippled in urine Hatched in fæces A, before treatment, B, intravenous edathamil, C, interval, D, penicillamine, E, interval, F, oral edathamil, G, interval, H, intravenous edathamil (1 day)

penicillamine had much less effect No drug affected the fæcal lead excretion, which fell progressively

There was no change in the blood-lead content as a result of treatment in cases 1, 2, and 3, where the mean blood-lead figures on admission were 51, 63, and 56 µg per 100 g respectively The highest values were found in case 4 (on admission 86, 89, and 89 µg per 100 g on consecutive days) and within a month the level had fallen to 50–60 µg per 100 g

The urinary coproporphyrin excretion was very variable from individual to individual and from day to day The mean pre treatment levels in cases 1, 2, and 3 were 12, 46, and 13 µg per day and there was no significant change during or as a result of treatment Before treatment there was a mean excretion of 142 µg per day in case 4, which fell to 30–60 µg per day within a month

Subjective improvement in cases 1, 2, and 3 was gradual but punctuated by mood swings and occasional emotional outbursts After discharge all but one of the men said that they felt better when taking edathamil $CaNa_2$ by mouth but there was no other correlation between treatment and the relief of symptoms The exception (case 2) complained that the abdominal discomfort and diarrhœa from which he had suffered periodically for 2 years was aggravated by oral edathamil $CaNa_2$ No other symptoms referable to treatment were noted No patient showed any desire to commit suicide

DISCUSSION

The treatment of tetraethyl lead poisoning should protect the patient against the ill effects of the substance and hasten his recovery by increasing the excretion of lead in a non-toxic form

All but the very mildest cases should be admitted to hospital Good nursing is essential to maintain hydration and nutrition and physical restraint may be necessary because of violence or suicidal attempts

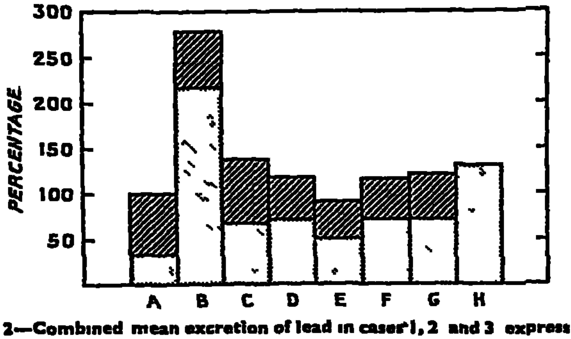

Fig 2—Combined mean excretion of lead in cases 1, 2 and 3 expressed as percentage of combined mean excretion before treatment Stippled proportion in urine Hatched proportion in fæces

Sedation with barbiturates is usually adequate in mild cases (cf cases 1 to 3), but in more severe cases it may aggravate the confusion and restlessness which become worse as the dose is increased in an attempt to control them In case 4 the patient was upset in this way by amylobarbitone in doses as small as gr 3 He tolerated paraldehyde by intramuscular injection much better

Means of Increasing Lead Excretion

Dimercaprol (B A L) and edathamil $CaNa_2$ are the only drugs available which effectively increase lead excretion and are suitable for clinical use They have been used extensively in inorganic lead poisoning and of the two, edathamil $CaNa_2$ is the less toxic and more effective Little is known of their value in tetraethyl lead poisoning

Though dimercaprol causes a transient increase in urinary lead excretion and a fall in blood lead level (the latter apparently by transfer to muscle and bone) which may relieve the symptoms of chronic inorganic lead poisoning, its frequent side effects—particularly nausea vasomotor symptoms and pain and necrosis at the site of injection—detract considerably from its value (Ryder et al 1947) Further, Graham and Hood (1948) have shown in animals and Vigliani and Zurlo (1951) in man, that it may aggravate acute poisoning Kehoe (personal communication 1951) and Kitzmiller et al (1954) do not regard it as valuable in the treatment of tetraethyl lead poisoning and we did not think its use was warranted

Edathamil calcium disodium is the monocalcium disodium complex of ethylene diamine tetracetic acid (edathamil, E D T A , versene), a chelating agent which combines with metallic ions forming non ionised, biologically inactive compounds Metals are displaced from the complexes by heavier metals In clinical practice the monocalcium disodium complex of edathamil is used to avoid reduction of the ionised serum calcium and it is the calcium atoms which are exchanged for those of heavier metals

Edathamil $CaNa_2$ has revolutionised the treatment of inorganic lead poisoning Most workers (Hardy et al 1954, Giles et al 1955, Wade and Burnum 1955) have given the drug intravenously in doses up to 1 g per 30 lb body-weight per day Symptomatic relief is rapid Colic disappears in a few hours (Marcus and Spencer 1955) The urinary lead excretion increases and is usually maximal on the first day of treatment, as in our cases of tetraethyl lead poisoning Side effects are uncommon but include malaise, joint pains and light headedness

Little work has been published on oral administration but Sidbury et al (1953) demonstrated a fivefold to tenfold increase in urinary excretion in inorganic lead poisoning and mentioned abdominal pain and diarrhœa as a side effect One of our patients, who had suffered from occasional abdominal pain and diarrhœa for 2 years, attributed an episode to oral edathamil $CaNa_2$

Nothing has been published in the British literature and the only report from America on the treatment of tetraethyl lead poisoning with edathamil $CaNa_2$ is that of Kitzmiller et al (1954), who treated three cases by intravenous infusion As in our experience and in contrast to that in inorganic lead poisoning, improvement was not dramatic and the increase in urinary lead excretion was relatively less than that found in inorganic lead poisoning Unfortunately detailed comparison between their results and ours is impossible because they collected only random urine and no fæcal samples

Penicillamine (ββ dimethyl cysteine), like dimercaprol contains 2 thiol (—SH) groups per molecule Walshe (1956) has shown that it increases the urinary excretion of copper in normal subjects and that in patients with hepatolenticular degeneration it does so as effectively as dimercaprol in doses containing equivalent amounts of sulphur The drug is given orally (300 mg t d s) and is apparently non-toxic It was given in these cases to see whether it would increase lead excretion without side effects There was little effect on lead excretion but no toxicity

The Psychiatric Side

The illnesses of our patients agreed closely with the descriptions of Machle (1935) and Kehoe (1925) and the manifestations were coloured by their underlying personalities In cases 1 and 3 the patients had stable personalities and a sense of responsibility They were worried by their illness, the first because he was responsible for the work and safety of the team and the third because he had to support a wife and young children The other two were unmarried and irresponsible The fourth patient in particular was known to drink heavily and to have been excitable He absorbed a considerable amount of tetraethyl lead over a short period and his intense excitement and violence were probably conditioned by his cyclothymic personality and aggravated by withdrawal of alcohol He was deliberately not given alcohol because this may further aggravate the toxic effects of tetraethyl lead It is probably significant that his " black out " before admission occurred in a public house although he had been warned not to take alcohol

E C T—Although Roth and Rosie (1953) have reported that E C T may produce striking improvement in toxic psychoses when the underlying cause has been treated, we know of no previous work on the effects of E C T in tetraethyl lead poisoning The response of case 4 was dramatic If other severely ill patients benefit in the same way, the problems of management and treatment would be simplified and mortality would probably be reduced

Summary

Four non fatal cases of tetraethyl lead poisoning are described The urinary lead excretion of the three studied in detail was increased sevenfold by edathamil $CaNa_2$ given intravenously, but little affected by edathamil $CaNa_2$ or by penicillamine by mouth One patient who was maniacal, hallucinated and deluded responded dramatically to electroconvulsion therapy

We wish to thank Dr J D N Nabarro for permission to study the patients, who were admitted under his care, Dr E L Udwin, who undertook the care of case 4 at Horton Hospital, Dr M Chapman, who gave the intravenous infusions and assisted in the collection of samples, Dr J M Walshe, who provided the penicillamine, Dr G Harrison, under whose direction the lead and coproporphyrin estimations were performed in the laboratory of the Associated Ethyl Company Limited, and the staffs of the clinical laboratories of the Courtauld Institute of Biochemistry and the Bland Sutton Institute of Pathology of the Middlesex Hospital Medical School who undertook other investigations and estimations

HYPOTHERMIA BY INTERNAL COOLING*

H H KHALIL
M B Alexandria, Ph D Lond
LECTURER IN MEDICINE, UNIVERSITY OF ALEXANDRIA

ARTIFICIAL hypothermia was first produced in mammals by Andjus (1951), who showed that albino rats so cooled could survive prolonged respiratory and cardiac arrest It has since been successfully used in man both as an aid to surgery (Lewis and Taufic 1953) and as an aid to anæsthesia Any method that is used for producing hypothermia can also be used for combating hyperpyrexia

There are at present two recognised methods of producing hypothermia surface cooling and extracorporeal blood cooling

Surface cooling is the more widely adopted method at present The patient's skin is cooled by putting him in cold water, a refrigerated blanket, or a box through which cold air is pumped Although surface-cooling is easy and generally applicable, particularly to small children, it takes a lot of time, and the body-temperature is difficult to control because it continues to fall after the surface cooling has been stopped Delorme (1953) and Brock (1956) have criticised this method because of undesirable effects

Extracorporeal blood-cooling was introduced by Boerema et al (1951) and Delorme (1952) Originally blood was taken from a large artery—e g, the femoral artery—cooled as it flowed through siliconed tubing immersed in cold water, and returned into a big vein Later vein-to-vein blood-cooling, using the venæ cavæ, was introduced by Ross (1954) Extracorporeal blood-cooling induces hypothermia more quickly than does surface cooling For cardiac surgery it has the advantage that it need not be started until the heart has been examined at operation Conversely, because it involves thoracotomy and cannulation of the venæ cavæ, it is clearly unsuitable for the other applications of hypothermia Even in cardiac surgery it adds further trauma to the heart and chest walls, and it is known to be associated with a high incidence of arrhythmias and ventricular fibrillation during cooling and operation Œdema of the brain has also been reported to follow the use of this technique

The difficulties and limitations in the above-mentioned two methods of producing hypothermia suggest that a simpler and safer method would be welcomed

Internal Cooling

Theoretical

The idea of producing hypothermia by filling the stomach with cold water in a balloon was suggested because of the rich vascularity of the gastric mucosa and the close relation of the stomach to the great blood-vessels of the abdomen and to important viscera, such as the liver All the major vessels of the abdomen lie in the stomach bed for a considerable length of their course, and so blood passing through them may be cooled in situ without having to be pumped outside the body and then back to the patient's circulation With each heart beat about half the arterial circulation of the body passes through the arteries lying behind the stomach, and the same volume is subsequently returned to the heart through the neighbouring veins A temperature gradient of a fraction of a degree between the large volume of blood flowing through these great vessels and the rest of the body tissues would affect the body-temperature considerably The large volume of blood cooled in this way at a small temperature gradient between it and the

sensitive vital organs would cool the body in a more uniform and gentler manner than where a small volume of blood is exteriorised, passed through a refrigerant, and then put back into the circulation at a wide temperature difference. Further, direct cooling of the abdominal viscera around the stomach will be an additional factor in cooling the body. This may also act by lessening the production of heat.

Experimental

In 1954 my preliminary experiments at Guy's Hospital on twenty rabbits showed that, by letting ice-cold water flow inside an intragastric balloon, the rabbits' body-temperature could be lowered from 39°C to 20°C and their heart-rate slowed from 250 to 60 beats a minute. They survived the experiment with no residual ill effects and were subsequently kept under observation for several months. Electrocardiograms during cooling showed bradycardia, prolonged conduction (P–R and QRS) and delayed repolarisation (S–T). Arrhythmias were rare, and ventricular fibrillation was never observed. There was no obvious change in the rabbits' behaviour after these experiments, and they did not lose weight.

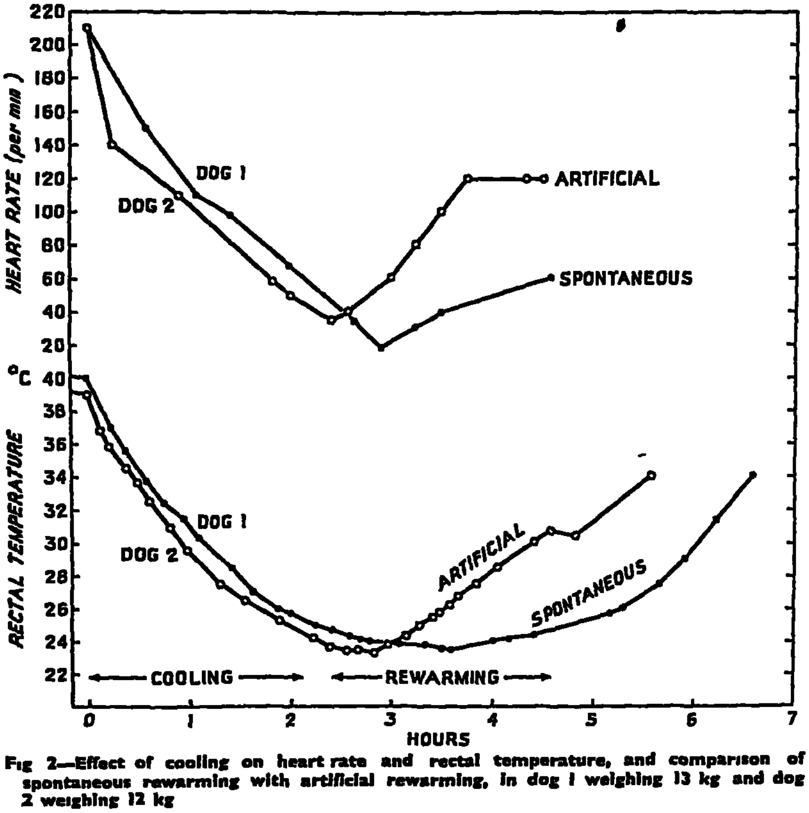

Fig. 2—Effect of cooling on heart rate and rectal temperature, and comparison of spontaneous rewarming with artificial rewarming, in dog 1 weighing 13 kg and dog 2 weighing 12 kg.

Clinical Trial

This technique of cooling by intragastric balloon was then tried with success on a hyperpyrexial baby (Khalil and MacKeith 1954). This case is of particular interest because surface-cooling with ice and fans had previously been tried for six hours without success, whereas internal cooling by the intragastric cold-water balloon improved the child's condition within a few minutes. The efficiency of this technique for cooling in man was evident. It was then decided to develop a practical apparatus for changing the body temperature by continuous infusion of cold or warm water through an intragastric balloon.

Materials and Methods

All the experiments were made in an air-conditioned room at 23°C. The subjects of the experiments were fourteen mongrel dogs weighing 12–20 kg and unselected as regards age and sex. Water was stored in two 160 litre tanks 1·5 m above the operating table. The water in one tank was cooled by mixing it with broken ice. Cold water passed down by gravity from the tank through rubber tubing to the balloon through the outer part of a double tube made of Porges 'Neoplex' (fig. 1, A) and left the balloon through the inner tube (fig. 1, B). The balloon used in each of these experiments was an ordinary rubber condom applied to the outer tube and with its end surrounded by a wide rubber band to make the balloon waterproof. To ensure that the size of the balloon remained constant inside the stomach, the outlet tube was attached through rubber tubing to a water suction-pump, and the rate of water flowing to the balloon was controlled at 2 litres a minute by regulating the gravity flow from the tank and the speed of the water suction-pump. This was indirectly tested by weighing the balloon. Two sensitive thermometers (fig 1, C and D), which had been compared beforehand, were inserted into the T-pieces (fig 1, E and F) fixed in the rubber tubing carrying water into and out of the balloon. Two mercury manometers (fig 1, G and H) were also connected to the two rubber tubes. The manometer H, connected to the outlet tube, was only used at intervals when the inflow of water and the suction were stopped. In the last eight experiments the electric suction-pump was out of order, and its place was taken by a tap-water suction-pump, which proved very practical and noiseless but did not return the cold water from the balloon to the tank.

Procedure

The dogs were first weighed. They were then given a fluid diet for twenty-four hours. On the day of the experiment they were only given water. Under open ether anæsthesia the dogs' tracheas were intubated. As the dogs' body-temperatures dropped, less ether was required to keep them well anæsthetised. The dogs were left to breathe ordinary air during the experiment. Since less oxygen is required in hypothermia, no artificial respiration was used, to avoid disturbing the acid-base balance by washing out carbon dioxide from the circulation. Body-temperatures were read from a mercury thermometer inserted about 10 cm into the rectum. After a sample of gastric juice had been collected, the empty balloon was easily introduced into the stomach and filled with cold water, till it weighed about a twelfth of the dog's body-weight, with a 50 ml two-way syringe, as used in direct transfusion. The filling of the balloon was indicated by the circumference of the abdomen, a double pneumograph (Palmer) being placed on the abdomen and connected by a Y-piece to a mercury manometer, on which the respiratory movements produced excursions of about 1 cm. Filling the intragastric balloon with water raised the level of mercury in the manometer about 5 cm and lessened the respiratory excursions to 0·2 cm. The manometer was then disconnected and adjusted to read 0 on both sides, and this reading was maintained throughout the experiment by controlling the rate of flow of the water. In this way the size of the balloon was kept constant. The pressure in the balloon was also recorded at short intervals during the experiment by temporarily closing both inflow and outflow tubes and connecting the outflow tube to the mercury manometer (fig 1, H). During cooling a continuous flow of cold water at 4–5°C at a rate of 2 litres a minute was maintained.

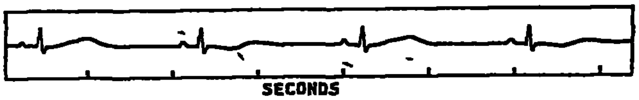

Fig 4—Electrocardiogram showing alternation in S–T segment in lead III at 23°C.

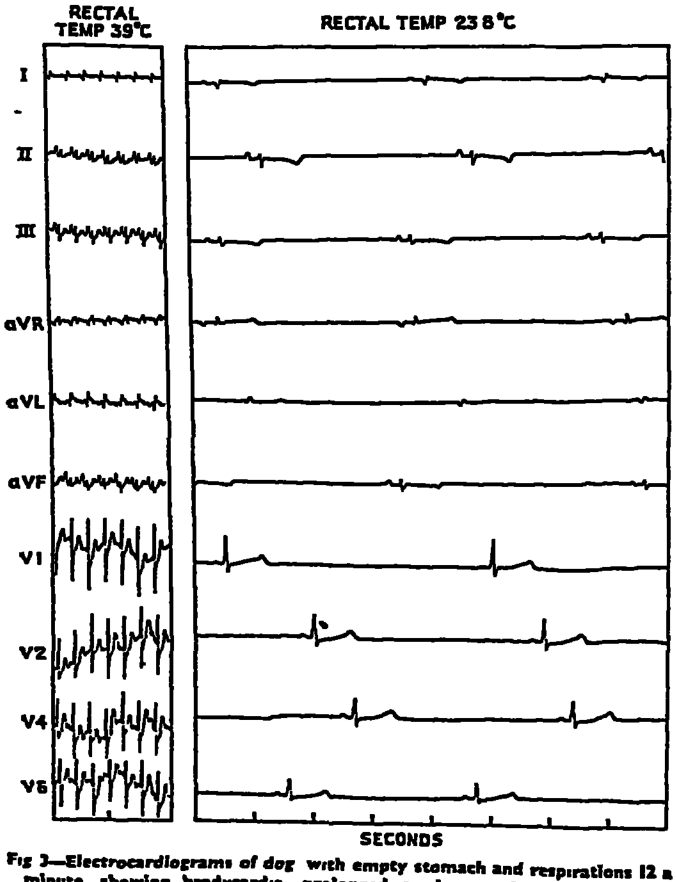

Fig 3—Electrocardiograms of dog with empty stomach and respirations 12 a minute showing bradycardia, prolonged conduction (P R and Q R S) and delayed repolarisation (S–T) at 23·8°C

Results

Although the intragastric balloon was filled till it weighed about a twelfth of the dog's body-weight, the epigastric region did not feel tense, and it seemed that there was room for more water. Possibly part of the balloon may have passed through the pylorus to the duodenum. The continuous flow of cold water inside the balloon lowered the body temperature and slowed the heart (fig 2) and respiration rates considerably. The fourteen unselected dogs were cooled from their normal rectal temperature of 39–40°C to one of 23·2–26°C, most of them to 23·2–24°C, and their heart rate slowed from 210 to 40 or thereabouts (fig 2). During cooling shivering was prevented by ether anæsthesia, which abolished the relevant reflexes. The dogs were left to themselves to rewarm, except that in the case of the last two warm water was circulated through the balloon. Without active rewarming, the rectal temperature went on falling and the heart-rate slowing (fig 2), and dogs cooled to 25°C warmed up much more quickly than those cooled to 23·2°C. With the onset of shivering the rectal temperature and heart and respiration rates rose, at first gradually and later rapidly. The dogs became semiconscious when their rectal temperature reached 27–28°C, they could sit and move at 30°C. Once started, the return of body-temperature to normal and the recovery of consciousness were remarkably rapid, even in the dogs which were not artificially rewarmed. On the morning following the experiment, the dogs looked well and took bread and milk readily. On the next day they ate a normal diet including meat and bones. Their subsequent steady increase in weight showed that their digestive function was not impaired by the procedure.

Electrocardiograms (fig 3) show most of the changes previously reported in hypothermia in dogs: bradycardia, prolonged conduction (P–R and Q R S), and delayed repolarisation (S–T), but arrhythmias were rare. A few ventricular extrasystoles developed at 24·5°C on two occasions but disappeared 5 minutes after warm water (35°C) had been passed through the balloon. No ventricular fibrillation developed The injury potential described by Osborne (1953) as the precursor of ventricular fibrillation appeared at about 29°C in four experiments but *did not lead to ventricular fibrillation, though some of the* dogs were cooled to below 25°C for a considerable time (fig 2) In one instance an alternation in the S–T segment appeared at 23°C (fig 4) The same thing happened in an experiment on a rabbit at the same temperature two years ago No adequate explanation has yet been put forward by numerous authorities who have seen the electrocardiogram

Discussion and Conclusions

This method is best named internal cooling It probably acts by cooling the blood in the large abdominal vessels and cooling the viscera

The low injury potential in the electrocardiograms, the rarity of arrhythmias, and the absence of spontaneous ventricular fibrillation were striking, this may be due to a gentler and more uniform cooling With extra-*corporeal cooling of the blood the heart receives cooled blood at many degrees below the body-temperature* Such cold blood does not readily give up its oxygen (Barcroft and King 1910), and this may affect the excitability and conductivity of the heart

The absence of trauma to the heart or great vessels is another attraction to this method of internal cooling

The organ most likely to suffer by this technique is the stomach The gastric functions have not yet been thoroughly investigated after internal cooling, but the early return of appetite and the absence of any gross evidence of permanent gastric dysfunction are good evidence that the stomach wall tolerates the procedure In the few dogs in which hydrochloric acid and pepsin were estimated there was no significant change a week after cooling Certainly in man the stomach is accustomed to wide variation in the temperature of the food it receives

Internal cooling may overcome some of the difficulties met with in current methods of producing hypothermia It is simple, practical, and easy to manage, and has given good results in one human case of hyperpyrexia, in which surface cooling had failed It does not interfere with the field of operation and so can be started at any time before or during the operation Internal cooling is almost as quick as extracorporeal cooling, and internal rewarming can be started during the operation as soon as hypothermia is no longer required Internal cooling combines the main advantages of the two other methods, and if it proves as successful in man as it has been in dogs it may even widen the field of application of hypothermia Intragastric cooling might be combined with intrarectal cooling or with surface cooling Such combinations might render the process of cooling quicker and more uniform and achieve lower hypothermia with safety Work is in progress to apply this method in man

Summary

A new method of inducing hypothermia in dogs by circulating cold water through an intragastric rubber balloon is described

This method was used on 14 animals and proved quite simple and practicable The rectal temperature was brought down to 25–23°C, and the heart rate from about 200 to about 40 per minute All the animals recovered quickly and apparently completely E C G tracings showed a striking absence of injury potential when the rectal temperature was above 29°C Injury potential appeared below this temperature in 4 out of 16 experiments, but it did not develop or lead to ventricular fibrillation

I thank Prof M L Dwidar for permission and facilities to conduct this work in the department of surgery, Alexandria University, Dr R C Mac Keith for his encouragement guidance, Dr P A Fleming for his help in interpretin electrocardiograms, Dr A S Soliman for his help in experiments, and Mr M S Mikhail for valuable tech assistance

IT is widely believed that most cases of sarcoid represent a peculiar form of reaction to the tube bacillus This supposition rests on an impressive b of circumstantial evidence, but attempts to prove it demonstrating tubercle bacilli in the sarcoid lesion ha with a few exceptions, met with failure One suggest put forward to explain their absence is that the bac having initiated the aggregation of histiocytes, rapidly destroyed by them in the sarcoid follicle (Ky 1921, Pinner 1938)

The primary purpose of the work reported here to test this hypothesis by observing whether attenua tubercle bacilli of the strain B C G survive, when ino lated into the skin of patients affected by sarcoido This experiment also provided an opportunity re-examine the claim made by Lemming (1940, 19 that the histological pattern at the site of such injection is peculiar to the disease and may therefo lend support to the diagnosis

10 patients suffering from sarcoidosis volunteered cooperate in the investigation They were given intracutaneous injection (0 1 ml) of a suspension B C G vaccine prepared by the *Danish Serum Institu* containing 0 5 mg of bacilli per ml The rate of develo ment of the local reaction was recorded Six weeks la the skin at the site of vaccination was excised a subjected to bacteriological and histological examinati

Clinical Features

The clinical and radiological manifestations of sa coidosis, uncommon in themselves, are unlikely to met in combination in any other disease *The diagno* in the 10 cases reported here was based on the *concurren* of two or more of these features The prevalence uveitis and of the intrathoracic manifestations of sa coidosis amongst them is to be attributed to the fa that most of the patients were under the joint care of eye hospital and a chest clinic

There were 8 women and 2 men, and they we between 24 and 55 years of age Uveitis was the cause the presenting complaint in 5 cases, in all of which it w

associated with symmetrical enlargement of the hilar lymph-nodes, reticulation of the lungs, or both In addition to these findings in this group, chronic enlargement of the parotid glands was found in 1 patient and raised plasma globulins in another In 2 of the 5 cases of uveitis the jelly-like nodules in the iris and the large "mutton-fat" corneal precipitates were in themselves suggestive of sarcoidosis

*Amongst the other 5 patients, 3 showed the charac*teristic radiological pattern of symmetrical reticulation of the lungs, associated with bilateral enlargement of the hilar lymph-nodes Of these 1 had cutaneous sarcoid lesions, confirmed by biopsy, in another the lymph-nodes in both axillae were considerably enlarged, and in another the plasma globulins were raised Of the other 2 patients, one presented with erythema nodosum and symmetrical enlargement of the hilar lymph-nodes, and the other showed similar hilar appearances with a group of enlarged lymph-nodes above the left clavicle Primary tuberculosis was excluded in both by a series of negative tuberculin tests The salient clinical features of each case are set out in the accompanying table

Activity of the disease was assessed by progressive change in the radiological pattern of the lungs, variation in the size of the lymph-nodes, fluctuation in the severity of the uveitis, pyrexia, or a raised sedimentation-rate Some evidence of activity was found in each of the 10 patients at the time, or during the weeks immediately after the inoculation with B C G vaccine

Tuberculin Tests

The tuberculin sensitivity of each patient was tested with intracutaneous old tuberculin (O T) in doses of 0 01–1 mg, just before, and again six weeks after inoculation with B C G vaccine One patient was given an additional test with 10 mg of O T

The results of the tuberculin tests are shown in the table 6 patients were initially tuberculin negative, and 2 of the remaining 4 gave a positive reaction only to 1 mg of O T Conversion of tuberculin sensitivity six weeks after inoculation with B C G vaccine occurred in only 2 of the negative reactors and no rise of sensitivity was observed amongst the initially positive reactors

1 patient lost his tuberculin sensitivity after B C G inoculation

Development of the B C G Lesion

In healthy subjects the *inflammatory changes at the* site of inoculation may set in within a few hours or may be delayed for several days The delayed reaction, commonly seen in tuberculin-negative subjects, begins after an interval of five to seven days with a small area of erythema which slowly grows into a papule and ulcerates three to six weeks after inoculation The immediate reaction on the other hand starts within twenty-four hours and progresses to an ulcerated papule in a few days It represents the Koch phenomenon and is usual in tuberculin-positive subjects In either event the inflammatory reaction is generally confined to the site of inoculation, though the regional lymph nodes occasionally *become enlarged*

In our series the delayed reaction was observed in 7 patients, the immediate reaction in 2, while in 1 tuberculin-negative patient the rate of development of the B C G lesion was not recorded Correlation with tuberculin sensitivity was not complete, since the reaction was delayed not only in the tuberculin negative patients but also in 2 of the 4 initially positive reactors The appearance of the B C G lesion was identical with that seen in healthy subjects The regional lymph nodes were examined in 4 patients (cases 3, 7, 9, and 10) six weeks after inoculation, and were not palpable

Histological Findings

Despite the variety of its clinical forms, the microscopic lesions in the affected tissues in sarcoidosis are essentially similar This is the basis of the concept that the disease is a unity The histological appearance of the sarcoid lesion is that of a sharply defined follicular structure composed of epithelioid cells These follicles occur singly or in groups, and may show an occasional multinucleated cell of Langhans type They do not caseate and do not appear to provoke any inflammatory reaction in the tissue in which they are found Classically there is practically no leucocytic infiltration of a follicle other than an occasional *lymphocyte*

In this investigation we found that B C G vaccine produced a granulomatous lesion with an occasional follicle and Langhans giant cell, with a considerable infiltration of polymorphs and histiocytes, as well as lymphocytes The appearances in no instance were typical of sarcoid lesions In 2 cases acid fast bacilli were seen in the granulomata

Bacteriological Investigations

In an attempt to recover the strains of organisms used for vaccination, the cutaneous nodules were excised at the end of six weeks in all cases Part of the tissue was used for histological examination, while in 8 cases the remainder was ground up in sterile saline, treated by Jungmann's concentration method, and the deposit cultured on Lowenstein Jensen medium In 1 of the 2 specimens not cultured, acid-fast bacilli were seen in stained histological sections

From 6 of these cultures a growth of *Mycobacterium tuberculosis* was obtained, morphologically and colonially identical with the original B C G strains From each of three growths a suspension of the bacilli was made in sterile saline and injected intramuscularly into a guineapig, one month later, in all 3 cases the animals showed a positive Mantoux reaction to 1 mg O T, having been previously negative

For comparison of staining reactions, appearance, cultural characteristics, and immunising power, organisms were used (1) taken directly from fresh ampoules of B C G vaccine, (2) from cultures of these on Lowenstein-Jensen medium, and (3) from cultures of swabs taken from the skin ulcers of vaccinated, non-sarcoid, tuberculin negative subjects

Since the guineapigs' immunological response to sarcoid-passed B C G vaccination was as expected, no attempt was made to elaborate the experiment of "challenging" them with a fully virulent strain of *M tuberculosis*

Discussion

These observations show that attenuated tubercle bacilli survive in the skin of patients affected by sarcoidosis They are apparently unaffected by the passage, since their form, staining properties, rate of growth, and appearance in culture, as well as their power to induce tuberculin conversion in the guineapig, were identical with those of the B C G strain obtained from other sources

It is difficult to assess how far an experiment of this type approaches the conditions under which tubercle bacilli are supposed to initiate the cutaneous manifestations of sarcoidosis The bacilli injected were presumably far in excess of the number which might lodge in the skin by dissemination under natural conditions On the other hand, the bacterial population is known to decrease considerably soon after vaccination (Birkhaug et al 1949, Gernez-Rieux et al 1950), so that for much of the time local conditions may have resembled those of a natural infection

The survival and rate of growth of tubercle bacilli in living tissues depends upon their virulence Mackaness et al (1954) found the strain B C G particularly vulnerable in experimental infections of the mouse and in cultures of rabbit monocytes The monocytes of the sarcoid granuloma are credited with enhanced powers of destroying tubercle bacilli, yet, in our experiments, bacilli of low virulence, unprotected by necrotic material or fibrous tissue, managed to survive for six weeks among a collection of such cells

The absence of enlargement of the regional lymph nodes draining the site of vaccination deserves comment Adenopathy is a common feature of sarcoidosis, and if the disease is in fact due to an infection, enlargement of the lymph-nodes could reasonably be attributed to invasion by the infecting organisms 3 of the 4 cases in which the state of the lymph nodes draining the site of vaccination was recorded had enlarged mediastinal glands, yet none of them developed palpable regional glands after vaccination If the tubercle bacillus was responsible for the mediastinal lymphadenopathy, one might have expected the lymph-nodes on the direct path of invasion from the site of vaccination to be similarly affected

The histological appearance of the B C G lesion in sarcoidosis is not distinctive enough to be used as a diagnostic test The pattern is that of a chronic inflammation with histiocytes and lymphocytes predominating As might be expected in an ulcerated lesion exposed to secondary infection, polymorphonuclear cells were also common Giant cells were not always present and never contained the inclusion bodies described in sarcoidosis No section showed the characteristic cell arrangement of the sarcoid follicle

Such a histological picture resembles the B C G lesion in healthy tuberculin-negative subjects, described by Sagher et al (1954), and suggests that, in many cases of sarcoidosis at any rate, the tissue response to B C G conforms to the normal pattern Bjornstad (1948), after comparing the histology of skin lesions produced by killed human and bovine bacilli and by B C G in sarcoidosis with that in healthy tuberculin-negative subject came to the same conclusion The claims of Lemming (1940, 1942), Warfvinge (1945), and Schaumann and Seeberg (1948) that the histological response to B C G in sarcoidosis is peculiar to this disease, could not be substantiated

The tuberculin tests confirmed the findings of Israel et al (1950) that failure of conversion after B C G vaccination is common in sarcoidosis

The rate of development of the B C G lesion conformed in general with that of normal subjects, according to their tuberculin sensitivity Leider and Sulzberger (1949) noted that, in 4 cases of sarcoidosis with cutaneous manifestations, the papule at the site of the B C G vaccination appeared earlier than in the controls and did not progress to ulceration In our series, including 1 patient with cutaneous nodules, the naked eye appearance of the B C G lesion was similar to that seen in healthy subjects at all stages of its development We came to the conclusion that the histological and naked eye appearance of the B C G lesion in sarcoidosis does not help to establish the diagnosis

Summary

Tubercle bacilli of the strain B C G inoculated into the skin of patients affected by sarcoidosis can be recovered six weeks later and are unaffected by passage

The rate of development and naked eye and histological appearance of the B C G lesion are not sufficiently distinctive to be relied on as a diagnostic test

We wish to record our thanks to Mr A G Cross for referring patients under his care at the Eye Sanatorium, Swanley, to one of us We are also indebted to Dr C H R Knowles for his report on the skin biopsy tissue in the first 3 cases, and to Dr E H Bailey for his valuable help in the bacteriological work

PLASMA-ŒSTROGEN LEVELS
IN LATE PREGNANCY, IN THE NORMAL MENSTRUATING FEMALE, AND IN THE MALE

J R K. Preedy
M D Camb , M R C P
RESEARCH FELLOW IN MEDICINE

Elsie H Aitken
B Sc Glasg
SENIOR TECHNICIAN

MEDICAL UNIT, THE LONDON HOSPITAL, LONDON

The chemical determination of œstrogens in the blood presents serious difficulties not only because of the minute amounts present but also because of the presence of material which interferes with the known methods for œstrogen detection

During the elaboration of a technique for the chemical determination of the three main œstrogens (œstrone, œstradiol-17β, and œstriol) in urine (Aitken and Preedy 1956), it appeared that the same technique could be applied to the estimation of œstrogens in the plasma of pregnancy

Since the chemical estimation of the three œstrogens in plasma using adequate separation techniques, has not been reported before, it may be valuable to present our findings in a small series of subjects in late pregnancy, in normal females, and in males

Material and Methods

Six patients in normal late pregnancy were studied, together with six normal females in the luteal phase of the menstrual cycle, and five normal males

Blood was collected heparinised, centrifuged immediately, and the supernatant plasma separated About 8 ml plasma was used in the pregnancy cases, and about 18 ml in the menstruating females and in the males The plasma was made up to 100 ml with water and refluxed in 1 8-N HCl for 45 minutes The procedure of Aitken and Preedy (1956), which involves gradient elution partition chromatography and fluorimetry, was then employed

TABLE I—PLASMA ŒSTROGEN LEVELS IN NORMAL LATE PREGNANCY

Case no	Age	Week of pregnancy	Primiparous (P) or multiparous (M)	Œstrogen levels (µg per 100 ml plasma)		
				Œstrone	Œstradiol 17β	Œstriol
1	29	41	M	2 65	1 25	4 28
2	25	38	P	3 06	2 04	17 5
3	34	38	M	7 15	2 19	7 10
4	36	38	M	10 30	1 40	8 65
5	22	30	P	9 20	2 93	11 7
6	36	42	M	6 50	1 82	7 65

Results

Plasma œstrogen levels in the late pregnancy cases are given in table I The ranges are as follows œstrone, 2 65–10 3 µg per 100 ml , œstradiol 17β, 1 25–2 93 µg per 100 ml , œstriol, 4 28–17 5 µg per 100 ml A typical chromatogram from one of the pregnancy cases is shown in the figure The peaks due to the three œstrogens are labelled , the remaining peaks are due to interfering material.

Œstrogen levels in normal menstruating females are given in table II The levels are much lower than those in pregnancy, and in many instances are below the range that can be conveniently detected by this method, especially in respect of œstradiol 17β

Results in the five normal males are also given in table II In only one (case 1) was any œstrogen measurable

Discussion

As the accompanying figure shows, the separation technique elaborated for urine (Aitken and Preedy 1956) is quite satisfactory when applied to the plasma of late pregnancy The three œstrogens are not only widely separated from one another, but also from the relatively large peaks of fluorescent interfering material It is clear from this figure that, unless good separation is obtained, estimates of the amount of œstrogen present must be inaccurate

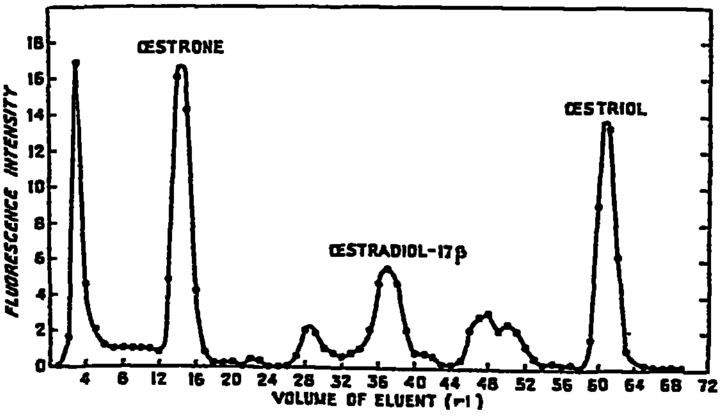
As part of an investigation into placental œstrogens Diczfalusy (1953) determined the œstrogen content of whole blood obtained from six pregnant women at parturition A fluorimetric technique similar to our own was used, but preliminary separation by 24-stage counter-current distribution, although adequate for pure œstrogen solutions, failed to give good separation of œstrogens from the interfering material in blood, especially in the first stages

TABLE II*—PLASMA-ŒSTROGEN LEVELS IN NORMAL MENSTRUATING FEMALES DURING THE LUTEAL PHASE AND IN NORMAL MALES

—	Case no	Age	Day of menstrual cycle	Œstrogen levels (µg per 100 ml plasma)		
				Œstrone	Œstradiol 17β	Œstriol
Females	1	21	25	0 215	<0 070	0 296
	2	20	23	0 134		<0 150
	3	22	24	0 145		
	4	21	25	<0 060		
	5	21	25			
	6	23	24			0 208
Males	1	38		0 111	<0 070	<0 150
	2	33		<0 060		
	3	35				
	4	32				
	5	33				

Œstrogen levels found in pregnancy plasma lie well within the sensitivity range of the present method As little as 8 ml plasma, or even less, is required for one estimation Serial determinations can therefore be performed in the same case

We decided to obtain plasma from the menstruating females during the luteal phase of the cycle, since Brown (1955) has shown that the urinary excretion of œstrone, œstradiol-17β and œstriol is highest during this phase Plasma œstrogen levels might then also be at their highest, although there is no evidence that urinary œstrogen levels accurately reflect those in the blood



A typical chromatogram of pregnancy plasma extract, showing the separation of œstrone œstradiol-17β, and œstriol obtained by gradient elution partition chromatography The unlabelled peaks are due to fluorescent interfering material typical of sarcoid lesions In 2 cases acid fast bacilli were seen in the granulomata

Bacteriological Investigations

In an attempt to recover the strains of organisms used for vaccination, the cutaneous nodules were excised at the end of six weeks in all cases Part of the tissue was used for histological examination, while in 8 cases the remainder was ground up in sterile saline, treated by Jungmann's concentration method, and the deposit cultured on Lowenstein Jensen medium In 1 of the 2 specimens not cultured, acid fast bacilli were seen in stained histological sections

From 6 of these cultures a growth of *Mycobacterium tuberculosis* was obtained, morphologically and colonially identical with the original B C G strains From each of three growths a suspension of the bacilli was made in sterile saline and injected intramuscularly into a guinea pig, one month later, in all 3 cases the animals showed a positive Mantoux reaction to 1 mg O T, having been previously negative

For comparison of staining reactions, appearance, cultural characteristics, and immunising power, organisms were used (1) taken directly from fresh ampoules of B C G vaccine, (2) from cultures of these on Lowenstein-Jensen medium, and (3) from cultures of swabs taken from the skin ulcers of vaccinated, non sarcoid, tuberculin negative subjects

Since the guineapigs' immunological response to sarcoid passed B C G vaccination was as expected, no attempt was made to elaborate the experiment of "challenging" them with a fully virulent strain of *M tuberculosis*

Discussion

These observations show that attenuated tubercle bacilli survive in the skin of patients affected by sarcoidosis They are apparently unaffected by the passage, since their form, staining properties, rate of growth, and appearance in culture, as well as their power to induce tuberculin conversion in the guineapig, were identical with those of the B C G strain obtained from other sources

It is difficult to assess how far an experiment of this type approaches the conditions under which tubercle bacilli are supposed to initiate the cutaneous manifestations of sarcoidosis The bacilli injected were presumably far in excess of the number which might lodge in the skin by dissemination under natural conditions On the other hand, the bacterial population is known to decrease considerably soon after vaccination (Birkhaug et al 1949, Gernez-Rieux et al 1950), so that for much of the time local conditions may have resembled those of a natural infection

The survival and rate of growth of tubercle bacilli in living tissues depends upon their virulence Mackaness et al (1954) found the strain B C G particularly vulnerable in experimental infections of the mouse and in cultures of rabbit monocytes The monocytes of the sarcoid granuloma are credited with enhanced powers of destroying tubercle bacilli, yet, in our experiments, bacilli of low virulence, unprotected by necrotic material or fibrous tissue, managed to survive for six weeks among a collection of such cells

The absence of enlargement of the regional lymph nodes draining the site of vaccination deserves comment Adenopathy is a common feature of sarcoidosis, and if the disease is in fact due to an infection, enlargement of the lymph nodes could reasonably be attributed to invasion by the infecting organisms 3 of the 4 cases in which the state of the lymph nodes draining the site of vaccination was recorded had enlarged mediastinal glands, yet none of them developed palpable regional glands after vaccination If the tubercle bacillus was responsible for the mediastinal lymphadenopathy, one might have expected the lymph-nodes on the direct path of invasion from the site of vaccination to be similarly affected

The histological appearance of the B C G lesion in sarcoidosis is not distinctive enough to be used as a diagnostic test The pattern is that of a chronic inflammation with histiocytes and lymphocytes predominating As might be expected in an ulcerated lesion exposed to secondary infection, polymorphonuclear cells were also common Giant cells were not always present, and never contained the inclusion bodies described in sarcoidosis No section showed the characteristic cell arrangement of the sarcoid follicle

Such a histological picture resembles the B C G lesion in healthy tuberculin-negative subjects, described by Sagher et al (1954), and suggests that, in many cases of sarcoidosis at any rate, the tissue response to B C G conforms to the normal pattern Bjornstad (1948), after comparing the histology of skin lesions produced by killed human and bovine bacilli and by B C G in sarcoidosis with that in healthy tuberculin negative subjects, came to the same conclusion The claims of Lemming (1940, 1942), Warfvinge (1945), and Schaumann and Seeberg (1948) that the histological response to B C G in sarcoidosis is peculiar to this disease, could not be substantiated

The tuberculin tests confirmed the findings of Israel et al (1950) that failure of conversion after B C G vaccination is common in sarcoidosis

The rate of development of the B C G lesion conformed in general with that of normal subjects, according to their tuberculin sensitivity Leider and Sulzberger (1949) noted that, in 4 cases of sarcoidosis with cutaneous manifestations, the papule at the site of the B C G vaccination appeared earlier than in the controls and did not progress to ulceration In our series, including 1 patient with cutaneous nodules, the naked eye appearance of the B C G lesion was similar to that seen in healthy subjects at all stages of its development We came to the conclusion that the histological and naked-eye appearance of the B C G lesion in sarcoidosis does not help to establish the diagnosis

Summary

Tubercle bacilli of the strain B C G inoculated into the skin of patients affected by sarcoidosis can be recovered six weeks later and are unaffected by passage

The rate of development and naked eye and histological appearance of the B C G lesion are not sufficiently distinctive to be relied on as a diagnostic test

We wish to record our thanks to Mr. A G Cross for referring patients under his care at the Eye Sanatorium, Swanley, to one of us We are also indebted to Dr C H R Knowles for his report on the skin biopsy tissue in the first 3 cases, and to Dr E H Bailey for his valuable help in the bacteriological work

PLASMA-ŒSTROGEN LEVELS
IN LATE PREGNANCY, IN THE NORMAL MENSTRUATING FEMALE, AND IN THE MALE

J R K PREEDY
M D Camb, M R C P
RESEARCH FELLOW IN MEDICINE

ELSIE H AITKEN
B Sc Glasg
SENIOR TECHNICIAN

MEDICAL UNIT, THE LONDON HOSPITAL, LONDON

THE chemical determination of œstrogens in the blood presents serious difficulties, not only because of the minute amounts present, but also because of the presence of material which interferes with the known methods for œstrogen detection

During the elaboration of a technique for the chemical determination of the three main œstrogens (œstrone, œstradiol-17β, and œstriol) in urine (Aitken and Preedy 1956), it appeared that the same technique could be applied to the estimation of œstrogens in the plasma of pregnancy

Since the chemical estimation of the three œstrogens in plasma using adequate separation techniques, has not been reported before, it may be valuable to present our findings in a small series of subjects in late pregnancy, in normal females, and in males

Material and Methods

Six patients in normal late pregnancy were studied, together with six normal females in the luteal phase of the menstrual cycle, and five normal males

Blood was collected, heparinised, centrifuged immediately, and the supernatant plasma separated About 8 ml plasma was used in the pregnancy cases, and about 18 ml in the menstruating females and in the males The plasma was made up to 100 ml with water and refluxed in 1 8 N HCl for 45 minutes The procedure of Aitken and Preedy (1956), which involves gradient elution partition chromatography and fluorimetry, was then employed

TABLE I—PLASMA ŒSTROGEN LEVELS IN NORMAL LATE PREGNANCY

Case no	Age	Week of pregnancy	Primiparous (P) or multiparous (M)	Œstrogen levels (µg per 100 ml plasma)		
				Œstrone	Œstradiol 17β	Œstriol
1	29	41	M	2 65	1 25	4 28
2	25	38	P	3 06	2 04	17 5
3	34	38	M	7 15	2 19	7 10
4	36	38	M	10 30	1 40	8 65
5	22	39	P	9 20	2 93	11 7
6	36	42	M	6 50	1 82	7 65

Results

Plasma œstrogen levels in the late pregnancy cases are given in table I The ranges are as follows œstrone, 2 65–10 3 µg per 100 ml, œstradiol 17β, 1 25–2 93 µg per 100 ml, œstriol, 4 28–17 5 µg per 100 ml A typical chromatogram from one of the pregnancy cases is shown in the figure The peaks due to the three œstrogens are labelled, the remaining peaks are due to interfering material

Œstrogen levels in normal menstruating females are given in table II The levels are much lower than those in pregnancy, and in many instances are below the range that can be conveniently detected by this method, especially in respect of œstradiol 17β

Results in the five normal males are also given in table II In only one (case 1) was any œstrogen measurable

Discussion

As the accompanying figure shows, the separation technique elaborated for urine (Aitken and Preedy 1956) is quite satisfactory when applied to the plasma of late pregnancy The three œstrogens are not only widely separated from one another, but also from the relatively large peaks of fluorescent interfering material It is clear from this figure that, unless good separation is obtained, estimates of the amount of œstrogen present must be inaccurate

As part of an investigation into placental œstrogens Diczfalusy (1953) determined the œstrogen content of whole blood obtained from six pregnant women at parturition A fluorimetric technique similar to our own was used, but preliminary separation by 24-stage counter current distribution, although adequate for pure œstrogen solutions, failed to give good separation of œstrogens from the interfering material in blood, especially in the first stages

TABLE II—PLASMA ŒSTROGEN LEVELS IN NORMAL MENSTRUATING FEMALES DURING THE LUTEAL PHASE AND IN NORMAL MALES

—	Case no	Age	Day of menstrual cycle	Œstrogen levels (µg per 100 ml plasma)		
				Œstrone	Œstradiol 17β	Œstriol
Females	1	21	25	0 215	<0 070	0 296
	2	20	23	0 134		<0 150

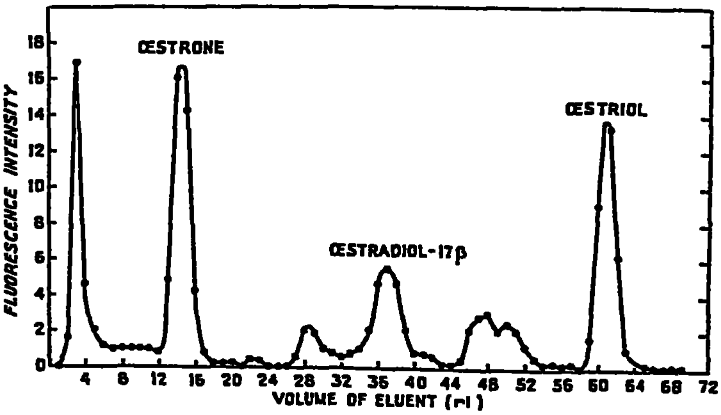
	4	32				
	5	33				

Œstrogen levels found in pregnancy plasma lie well within the sensitivity range of the present method As little as 8 ml plasma, or even less, is required for one estimation Serial determinations can therefore be performed in the same case

We decided to obtain plasma from the menstruating females during the luteal phase of the cycle, since Brown (1955) has shown that the urinary excretion of œstrone, œstradiol-17β and œstriol is highest during this phase. Plasma œstrogen levels might then also be at their highest, although there is no evidence that urinary œstrogen levels accurately reflect those in the blood



A typical chromatogram of pregnancy plasma extract, showing the separation of œstrone œstradiol 17β and œstriol obtained by gradient elution partition chromatography The unlabelled peaks are due to fluorescent interfering material

In spite of the use of much larger samples, however, only very small amounts of œstrogen could be detected in the plasma of the menstruating females Œstrone was measurable in three of the six cases only, and œstriol in two of the six cases No œstradiol-17β could be detected in any case The measured values can therefore be only approximate Furthermore, identification of the three œstrogens in these cases depends only on the finding of fluorescent peaks in the expected positions This is not entirely satisfactory

In the plasma of pregnancy, on the other hand, the œstrogen peaks in the chromatogram can be identified with reasonable confidence, because of the larger amounts of œstrogen present and the absence of any other immediately adjacent peaks Furthermore, the addition of pure crystalline œstrone, œstradiol 17β, and œstriol to pregnancy-plasma extracts resulted in a symmetrical increase in size of the three existing œstrogen peaks

The lowest amounts of œstrogen that can conveniently be detected in plasma by this method, using 18 ml, are œstrone, 0 06 μg per 100 ml, œstradiol-17β, 0 07 μg per 100 ml, œstriol, 0 15 μg per 100 ml

The state in which œstrogens exist in the blood is uncertain (Lieberman and Teich 1953) The distribution between plasma and cells is unknown, and the extent to which œstrogens are bound to plasma proteins is difficult to determine Œstrogens may occur in free form, or as glycoronides or sulphates In order to minimise the difficulties so created, it was decided to use plasma only, and to obtain figures for total œstrogen content by preliminary refluxing of the plasma for 45 minutes in 1 8 N acid This procedure denatures the plasma protein, and might be expected to release all œstrogen bound to the protein, although this would be difficult to prove At the same time œstrogen conjugates would be hydrolysed

It is known that uncombined œstrogens are resistant to refluxing in acid under these conditions (Marrian and Bauld 1951, Katzman et al 1954), and it therefore appeared unlikely that significant amounts of œstrogen would be destroyed by our procedure In addition, recoveries of pure crystalline œstrogens added to plasma before hydrolysis, extraction, and chromatography, were within the range of recoveries of œstrogen from urine reported by Aitken and Preedy (1956)

These results may provide a basis for the further study of plasma œstrogens, especially in normal and abnormal pregnancies Preliminary observations suggest that the method will also be of value in the study of plasma-œstrogen levels in hepatic disease

Summary

Plasma levels of œstrone, œstradiol 17β, and œstriol have been determined in pregnancy and in normal females and males by a chemical method, involving gradient-elution partition chromatography and fluorimetry

In pregnancy, the œstrogen concentrations were found to lie well within the sensitivity range of the method

In normal females and males, the concentrations were very low, and in several cases, no œstrogen could be detected

We should like to acknowledge our indebtedness to Prof C J O R Morris for constant help and advice We are most grateful to those colleagues and medical students who kindly gave blood for œstrogen determinations in the normal, and to the staff of the obstetric department, The London Hospital, for their cooperation in obtaining blood from the pregnant women

PULLED ELBOW

M R Salkind
MRCS
GENERAL PRACTITIONER, CLAPTON, LONDON

Subluxation of the head of the radius distally under the annular ligament, or "pulled elbow," is a distinct clinical entity seen in children, which deserves to be better known

It was first described by Fournier (1671), and later by Lindeman (1885) In the United States Magill and Aitken (1954) give as high an incidence as 3% of all children aged 8 years or less, attending a Boston fracture clinic over a period of two years In children under 5 years of age it is twice as common as supracondylar fractures of the lower end of the humerus (Plewes 1956) Its frequency in general practice must therefore be far from negligible

No case has been reported in anyone over the age of 8 This is accounted for by the change in size of the head of the radius relative to the size of its neck Up to 5 years of age the head is smaller than the neck (Piersol 1930), and can thus slip easily under the retaining band of the annular ligament The head increases in size relative to the neck until at 8 years it is actually larger and so is retained in position by the annular ligament

The diagnosis should be simple The history is usually that the child's extended arm was pulled when he was lifted to a higher position There is sometimes a snap, and the child is unable or unwilling to use the affected arm In some cases the child comes to the parent, crying and fretful, with his arm limp, and no history of a pull is obtainable, though there has certainly been one Often the child cannot refer complaints to any particular site, but at times he complains of pain in the shoulder, clavicle, or wrist This accounts for the multiplicity of diagnose which have been made Now that poliomyelitis is more common, sudden limpness of an arm is an important symptom

Physical signs are few—namely, limitation of supination, and occasional tenderness over the head of the radius Presence of a rubbery resistance to passive supination and extension beyond 160° has been described (Magill and Aitken 1954) Radiographs are always normal

Reduction is immediately effective and can dramatically relieve the symptoms The doctor's thumb is placed just behind the radial head and the child's forearm is supinated and extended Sudden supination has also been recommended (Plewes 1956) In most cases, the child can at once move the arm, crying and fretting cease forthwith

Where the diagnosis is not made, a sprain is usually suspected The unfortunate child then wends his way from doctor to clinic and back again until such time as the manœuvre is carried out, often accidentally in the course of a physical examination, or even whilst radiographs are being taken Recurrence is common—perhaps the initial dislocation in some way leads to this

Case-reports

Case 1 —This girl had three subluxations

First —At 10 months She was crawling along a balcony when her father, in alarm, pulled her back by the arm It became limp, and she was taken to the nearest doctor The dislocation reduced itself during the examination

Second —At 2 years She was pulled upright from a sitting position She cried out, and her arm became limp Her shoulder seemed tender, but was not dislocated Radiographs showed nothing abnormal and the mother was told that nothing was wrong and that the trouble would right itself She was seen that evening in surgery and was asked to attend next morning if no improvement had taken place She did so, and was sent to the local children's hospital There the correct diagnosis was made and treatment gave immediate relief

Third—At 3 years She came running into the house crying with the same arm limp She was taken to the surgery and treated by extension and supination She left holding her toys in her arms No history of pull was obtainable on this occasion

Case 2—A girl who suffered two subluxations

First—At 5 months She was sitting on her father's knee and fell backwards. Her left arm was caught as she fell, it became limp and she was very fretful She was visiting relatives at the time, and was taken to the nearest teaching hospital The casualty officer was unable to make a diagnosis, but the elbow clicked back into position while radiographs were being taken

Second—At 10 months There was an exact repetition of the first episode When she was brought to the surgery she had limitation of supination and tenderness over the head of the radius Extension and supination resulted in immediate freeing of the elbow-joint

Summary

In young children the head of the radius is smaller than the neck, and subluxation under the annular ligament is not rare After a pull, the arm becomes limp Reduction, by supination and extension with a thumb behind the radial head, gives immediate relief

AFFERENT-LOOP STRANGULATION FOLLOWING PARTIAL GASTRECTOMY

A CASE-REPORT

F C Hoyte
M B Lond, F R C S
LATE SURGICAL REGISTRAR

W H W Jayne
M B Lond, F R C S
SENIOR SURGICAL REGISTRAR

W K Pallister
M B Lond F F A R C S
LATE ANÆSTHETIC REGISTRAR

WESTMINSTER HOSPITAL, LONDON

A DESCRIPTION of 15 collected cases of small gut strangulation following partial gastrectomy has been given by Stammers (1954) and a further case is reported here It is unusual because it followed a short-loop antecolic anastomosis and was accompanied by a volvulus of the stomach Record is also made of the successful use of intra arterial transfusion in the resuscitation of the patient who was suffering from advanced non hæmorrhagic shock (Horton et al 1953)

Case-report

A man aged 47 came to the orthopædic outpatient department with pain in the back for two months He was found to have had melæna for five days and his hæmoglobin level was estimated to be 33% of normal Conservative treatment including blood transfusion was begun but after three days the pain grew worse and he vomited more than a pint of blood Immediate laparotomy was advised and although he had not complained of dyspepsia a giant benign ulcer was found on the lesser curve of the stomach for which partial gastrectomy was performed An ante colic Polya type of anastomosis was made with the afferent loop attached to the lesser curve and care was taken to ensure that the jejunal loop used was short

Postoperatively the abdominal wound ruptured and was resutured but despite this setback he made a good recovery and was discharged to a convalescence home

There on the 23rd day after the gastrectomy, he had severe pain in the back and left side of the abdomen it came on suddenly and gradually grew worse it was colicky and radiated to the left testis He vomited three times without relief Thirty hours later he was readmitted to hospital and signs of generalised peritoneal irritation, greatest on the left side, were noted His general condition was poor and it was apparent that he was suffering from advanced peripheral circulatory failure, the pulse rate was 110 per minute and the blood pressure 75/55 mm Hg (his normal was 120/80) It seemed that he had had a perforation of the gastro intestinal tract or possibly a delayed hæmorrhage from the spleen damaged during the gastrectomy Immediate operation was advised and, because of the possibility of hæmorrhage, he was taken to the theatre where resuscitation began Intravenous saline was used until compatible blood could be obtained His condition rapidly deteriorated and the systolic blood-pressure fell to 30 mm Hg, the respirations were gasping, and he appeared to be about to die When blood was available intra-arterial transfusion was performed using the right radial artery and two pints were given in seven minutes followed by a third more slowly There was an immediate improvement in his condition and respiration became more normal, at the end of twenty minutes the systolic pressure had risen to 75 mm and, as he was now better able to withstand operation anæsthesia was induced

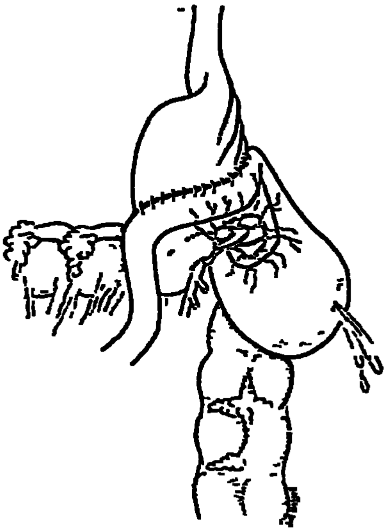

Diagram of operation findings

When the abdomen was opened through a left upper paramedian incision a loop of small gut was found in the left paracolic gutter It was distended to a diameter of 3 in and was discoloured green brown with a gangrenous patch in the centre of which was a perforation. Intestinal contents poured through the hole (see figure) Further search eventually showed that the stomach had undergone a volvulus through 180° about its long axis so that its posterior wall now faced anteriorly, the direction of the twist was such that the greater curve and efferent loop had passed in front and to the right, while the lesser curve and afferent loop had passed behind and to the left The distended gut first seen proved to be the afferent loop strangulated by the gap between the anastomotic jejunal loop and the transverse mesocolon, and it was hanging over the first jejunal branches of the superior mesenteric artery down into the left paracolic gutter The afferent and efferent loops were therefore replaced in their normal positions and the volvulus of the stomach untwisted The perforation which was not far from the duodenojejunal flexure, was closed and the gangrenous patch buried In order to prevent a recurrence the loops were fixed to the parietal peritoneum with a few interrupted catgut sutures During the operation further intra arterial blood was given, half a pint at a time, as indicated by the blood pressure, a total of four and a half pints was given and at the end of the operation the blood pressure had stabilised at 110/75 and a slow intravenous transfusion was now running He made a good recovery and when last seen in the outpatient department was well

Discussion

Strangulation of the small bowel as a complication of partial gastrectomy has been reported several times and may involve either the afferent or efferent loop We found in the literature 10 cases involving the afferent loop of an antecolic anastomosis, but in each one mention was made that a long loop was used, and in none of these cases was volvulus of the stomach noted (Quinn and Gifford 1950, West 1953, Stammers 1954)

It seems reasonable that the use of a short loop should avoid the complication of strangulation and has been advocated for that purpose That it does usually avoid it is probably borne out by the fact that, so far as we know, this is the first case recorded in which a short loop was used and it is hard to explain the mechanism of its occurrence It may be that this loop used was too short and formed a straight line with the œsophagus and lesser curve This could have acted as a firm pivot or bowstring about which the adjacent and more mobile portions of the gastro intestinal tract were able to rotate

In the early stages of shock intravenous transfusion increases the venous return to the heart, which responds with an improved output, and the distribution of the blood-volume begins to return to normal But in the later, or "irreversible," stage the cardiac output and blood-pressure are so low that the coronary circulation is inadequate and progressive myocardial depression ensues, it is this that prevents the usual response to intravenous transfusion and explains its failure to improve a shocked patient under these conditions At the same time there is anoxic damage to the liver, and this has been implicated in the development of shock, this damage, however, is reversed when the oxygen supply to the liver is improved

Because the arterial tree is a relatively closed system the pressure within it will be directly raised by pumping blood into it, in this way not only is the effective circulating blood volume rapidly restored but the blood pressure is raised so that increased coronary flow results and myocardial depression is reversed The progress of shock is arrested and the whole of the circulation now tends to return to normal and the oxygenation of the brain, liver, and kidneys is improved

The indications for intra-arterial transfusion in this case were the low blood-pressure and slowing pulse rate which suggested clinically that myocardial depression had set in (Wiggers 1949) We believe that the sequence of events following intra arterial transfusion in this patient was, in essence, as we have described, and that this accounts for the recovery of a man who had had an intraperitoneal perforation for more than thirty hours and had to undergo a major operation

Our thanks are due to Mr F d Abreu for permission to publish this report and to Dr R Wise who gave the anæsthetic on each occasion

THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON

AFTER the acute stage of poliomyelitis ventilatory capacity may be greatly reduced yet allow the patient to return home without artificial respiratory aid Such a patient is vulnerable to even a small further reduction of his respiratory reserve, which may lead to his admission to hospital as a respiratory emergency The following case illustrates the insidious onset of respiratory insufficiency 9 years after the attack of poliomyelitis, and is remarkable for the ease with which short periods of artificial respiration could profoundly disturb acid base balance

Case-report

A man aged 30 had had an attack of acute poliomyelitis 9 years before The respiratory muscles and limbs were extensively involved He was treated in a cabinet respirator for 14 months, and on discharge from hospital, 2 years after the onset, his vital capacity was about 1250 c cm At home he led mainly a bedridden existence, though he could walk a few steps His respirations seemed adequate until the beginning of June, 1956, when his breathing became noticeably shallower There was nothing to point to any specific illness though he was listless and unusually dry and thirsty

First Emergency

During the night of June 13, he lapsed into stupor and muttering delirium and next day he was admitted to another hospital where he was intubated and put into a cabinet respirator Despite this he became comatose He was then transferred to the National Hospital, Queen Square, on a Beaver positive pressure respirator His condition gradually improved and within 3 hours, though still drowsy, he could be roused sufficiently to answer questions The same evening, however, he again became comatose He was then being ventilated at 10 litres a minute Blood pressure was 85/50 mm Hg, pulse was regular at 100 a minute, blood sugar, blood urea, and serum potassium levels were normal

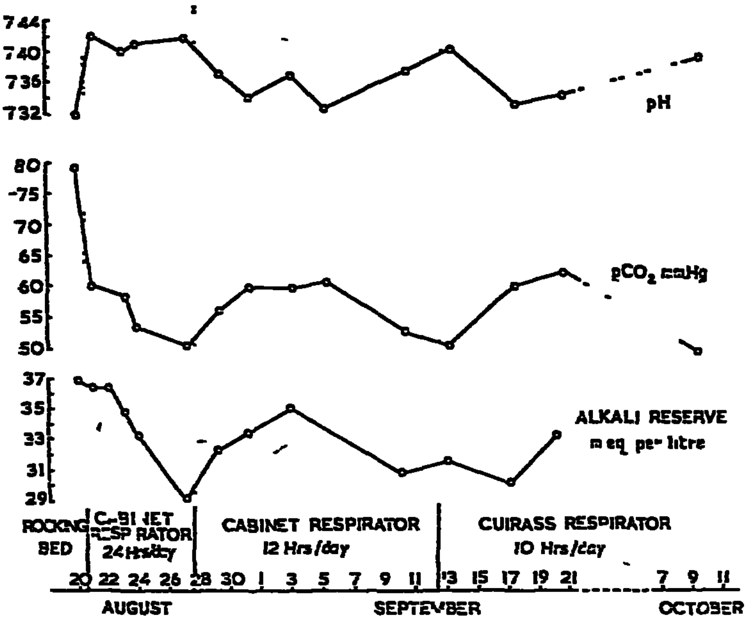
3 hours after the onset of this further relapse spontaneous muscle fasciculations were noticed in the upper limbs and a strongly positive Chvostek sign could be elicited These signs indicated that the patient had passed into a state of hypocapnic coma This conclusion was justified by an immediate and dramatic improvement in the conscious level when 3 litres a minute of a mixture of 5% CO_2 and 95% O_2 were added to the inspired air The muscle fasciculations ceased and the Chvostek sign disappeared after a few minutes The blood pressure rose slightly to 100/60 and the pulse rate remained constant

At midday on June 15, when he was being ventilated at 9 litres a minute including $1^1/_2$ litres of 5% CO_2 and 95% O_2 arterial puncture was performed The arterial O_2 saturation was 95%, the pH 7 57, and the pCO_2 (calculated by the Henderson Hasselbalch equation from the pH and plasma CO_2) was 30 mm Hg The alkali reserve was 30 2 m eq per litre This combination of a raised alkali reserve and lowered arterial pCO_2 indicated that respiratory and metabolic alkalosis were simultaneously present The metabolic alkalosis represented an attempted compensation for the previous respiratory acidosis resulting from his long standing chronic underventilation The respiratory alkalosis was due to the washing out of CO_2 by the artificial ventilation, and was still considerable even after several hours during which 5% CO_2 had been added to the inspired air There must have been, therefore, an even greater alkalosis when he was clinically in alkalotic coma

The patient was transferred to a cabinet respirator and the endotracheal tube removed His condition continued to improve so that by the 5th day weaning from the respirator could be begun On the 7th day, when his vital capacity had risen to 800 c cm, he was breathing unaided for an hour morning and afternoon At the end of one of these hour long periods the arterial O_2 saturation was 92%, with pH 7 36, pCO_2 51 mm Hg, and alkali reserve 31 7 m eq per litre Despite the mild degree of hypoventilation indicated by these results, his clinical condition appeared to justify his being left out of the respirator for increasing lengths of time, and on July 2 he was discharged

Second Emergency

On July 12 he was readmitted He had been well until that *morning, when he awoke* feeling listless, apathetic, and anorexic On admission he was rational but drowsy and cyanosed His respirations were shallow and the vital capacity was only 450 c cm The arterial O_2 saturation was 70%, the pH 7 37, the pCO_2 69 mm Hg, and the alkali reserve 35 m eq per litre He was put in a cabinet respirator at 7 30 P M and his cyanosis rapidly improved An hour later he became unresponsive, but when the rate of the machine was reduced from 20 to 16 cycles a minute he awoke and talked normally within 30 seconds At 9 15 P M he again became unresponsive



Effects of different forms of artificial respiration on pH, pCO₂ and alkali reserve. Determinations made on arterial or arterialised venous blood.

and exhibited a marked bilateral Chvostek sign. The pupils were constricted and did not respond to light, the corneal reflexes were absent, and there was marked muscle fasciculation. He was flushed and pink. The rate was reduced to 13 a minute, and within 20 seconds the pupils dilated widely and reacted to light through a small range. Within 50 seconds he became sufficiently conscious to answer simple questions and the Chvostek sign disappeared. During this episode the blood-pressure ranged between 105/70 and 110/90 and the pulse between 96 and 126 a minute. The loss of consciousness was therefore not due to circulatory collapse but to a lowering of the CO_2 tension in the blood by the artificial ventilation. Subsequent progress was satisfactory apart from a collapse of the left lower lobe, which re-expanded following bronchoscopic suction.

Preventive Measures

These repeated episodes of respiratory insufficiency clearly showed that this patient would continue to need some form of assistance to maintain adequate ventilation. An attempt was made over the next 4 weeks to wean him from the cabinet respirator to a rocking bed, since this would present few problems for home management and would be free from the danger of hyperventilation. Unfortunately, despite rocking for at least 12 hours each day, he gradually became so dyspnœic and lethargic that the rocking bed at this stage hindered rather than helped his breathing, since he was unable to synchronise his respirations with its movements. We therefore conducted a more detailed study of the blood gas and acid-base changes to decide on the most suitable form of respiratory aid.

These findings are illustrated in the figure. At the end of the period on the rocking bed the pCO_2 was 79 mm. Hg, the blood pH 7.32, and the alkali reserve 37 m.eq. per litre. The patient was again placed in the cabinet respirator and ventilated at 7–8 litres a minute. Within 24 hours the pCO_2 had fallen to 60 mm. Hg and the pH had risen to 7.42. At the end of a week, during which the pH remained at about 7.4, the pCO_2 had fallen steadily to 50 mm. Hg. The period in the respirator was then reduced to 12 hours each day, and though at first the alkali reserve and pCO_2 rose slightly, after about a week they again began to fall and the pH to rise.

Since CO_2 was thus not retained when the cabinet respirator was used for 12 hours a day, we decided to replace it with a cuirass respirator, and the figure shows that, after a similar initial few days for acclimatisation, 10 hours each night in the cuirass was sufficient to maintain ventilatory equilibrium. After 4 weeks of using the cuirass the vital capacity was 800 c.cm., the arterial oxygen saturation 91%, the pH 7.40, and the pCO_2 50 mm. Hg.

The patient was accordingly discharged home with his cuirass and has continued to make satisfactory progress.

Discussion

In patients with a grossly reduced vital capacity, a minor respiratory infection is known to be the commonest cause of respiratory failure, but it is not so widely realised that such a failure can take place without any obvious precipitating cause. Ferris et al. (1952) have demonstrated decreased compliance in convalescent poliomyelitis patients. This may be due to emphysematous changes in the lungs, produced by the artificial respiration, or to increase in the rigidity of the chest wall itself because its expansion is small. Such changes probably progress for several years after the original illness, the final stages of respiratory failure being precipitated by the increasing anoxia and rising CO_2 tension resulting from the impaired ventilation. Closer questioning of our patient's family revealed that there had been progressive reduction in his ventilation for the past 2 years, culminating in the respiratory failure of June, 1956.

The high alkali-reserve indicates a measure of compensation for such prolonged respiratory insufficiency. This metabolic alkalosis was responsible for the extraordinary rapid swing from hypercapnic to hypocapnic coma when effective artificial respiration was begun. We have never seen such a change in cases of acute respiratory failure, in which the onset is presumably too acute for any considerable compensatory metabolic alkalosis to arise. This seems to be borne out by Astrup et al. (1954) who, in a case of acute poliomyelitis, reduced the pCO_2 from 150 to 14 mm. Hg without untoward effects.

Even more startling than the ease with which our patient swung from hypercapnic to hypocapnic coma was his recovery of consciousness within a minute of reducing the rate of the cabinet respirator. The rapidity of this recovery was puzzling, since the reduction in ventilation could not have appreciably altered the arterial blood gas tensions in such a short period.

Although in this patient the fasciculation and the positive Chvostek sign helped to distinguish between hypocapnic and hypercapnic coma, these signs may be absent in hypocapnia, and Westlake et al. (1955) have described similar muscular irritability in hypercapnia following oxygen therapy in emphysema. Determination of the arterial pCO_2 is therefore a most valuable guide to the ventilatory state in these circumstances. Its value was further emphasised during the assessment of the most suitable type of respiratory aid for this patient.

Summary

A case of acute respiratory failure, 9 years after an attack of poliomyelitis, is described.

This patient showed an unusually rapid swing from hypercapnic to hypocapnic coma with only moderate artificial respiration.

The value of blood-gas analysis in assessing such disturbances of acid-base equilibrium and in selecting the most suitable type of respiratory assistance is illustrated.

We are grateful to the medical committee of the National Hospital, Queen Square, and to Dr. Michael Kremer, under whose care the patient was, for permission to publish this case; and to Dr. Kremer and Dr. R. Atwood Beaver for their advice.

Preliminary Communication

REAGIN CONTENT OF CHROMATOGRAPHIC FRACTIONS OF HUMAN GAMMA-GLOBULIN

SEVERAL attempts have been made to decide which of the electrophoretic fractions of human serum proteins contain the skin sensitising antibodies—the reagins Electrophoresis convection [1–3] suggested that reagins may be present *in any or all of the globulin fractions* However, zone electrophoresis on starch [4] and continuous electrophoresis [5] showed definite localisation of reagin activity in the γ-globulin and particularly in the faster moving γ^1-globulin fraction

We observed that slight modification of the Peterson and Sober [6] technique of chromatography of serum-proteins on diethyl amino ethyl cellulose gave, with human serum, one main γ globulin fraction together with several smaller fractions of γ-globulin When examined by paper electrophoresis, the main fraction was found to move distinctly more slowly at pH 8 6 than the small fractions (which were indistinguishable from each other) It appeared that a simple fractionation of the slower and faster moving γ-globulin had been obtained and that the γ^1-globulin was further subdivided into several reproducible fractions In view of the previous evidence that reagins are largely in the γ^1 fractions, it was decided to fractionate sera from allergic subjects and to test whether the reagins were localised in one or more fractions It was found that with sera from six people allergic to a variety of substances, reagin activity was always highest in one γ^1 fraction, and in most cases was almost confined to that fraction

EXPERIMENTAL

Chromatography

Diethyl amino ethyl cellulose was prepared as described by Peterson and Sober [6]

The buffers used for development were 0 01 M sodium phosphate pH 7 5, 0 02 M sodium phosphate pH 6 2, and 0 05 M NaH$_2$PO$_4$ All were saturated with toluene before use Gradient elution was not used Each buffer was run through until no further protein was eluted, and the next buffer was then added The column was equilibrated with the weakest buffer at 2°C and the serum sample dialysed against this buffer before running on the column at 2°C 3 ml serum were fractionated on a 3 g column (1 1 × 12 cm) with a rate of flow of about 5 ml per hour Estimation of protein concentration in the eluate was by measurement of the absorption at 280 mμ in 1 cm cell in a spectrophotometer

Assay of Reagins

The chromatographic fractions were concentrated by pressure dialysis against 0 14 M NaCl and the volume of each adjusted to equal the volume of serum put on the column (3 ml) The fractions were sterilised by filtration through 'Oxoid' membrane filters (Oxo Ltd, London, E C 4)

Assay was by the Prausnitz-Küstner [7] passive sensitisation test

0 1 ml of three dilutions of the serum fractions were injected intracutaneously into the skin of the forearm, thigh, or back, of volunteers who, by previous tests, had been shown to be insensitive to the antigen used The sites of injection were marked, and 48 hours later were challenged by pricking through drops of antigen solution A positive reaction consisted in the appearance of a weal and erythema which was maximal in about 15 minutes and disappeared in 1–2 hours The area of the weal at its maximum was estimated by measuring the diameter in two directions at right angles

Serum was obtained from members of the staff of this institute who had a history of hay fever and/or asthma and who were shown by skin tests to be sensitive to mixed pollens ('Pollaccine'), horse serum, or extracts of cat or dog scurf Only one of the subjects examined had had a course of desensitising injections of antigen

The blood was drawn aseptically from the arm, and was allowed to clot, and the serum was stored at −10 C

RESULTS

Fig 1 shows the elution diagram when 3 ml serum (J M) was run on a 3 g column

The fast peak has come through the column at the solvent front without adsorption and is certainly a mixture of several components, peak 2 is adsorbed and retarded to some extent in 0 01 M phosphate buffer 0 02 M buffer was then run through and two more peaks emerged, the shape of the first suggesting that it might contain two partially resolved components Finally with 0 05 M buffer a large complex peak appeared Peaks 1, 2, 3, and 4, when tested by paper electrophoresis at pH 8 6, proved to be all γ globulin

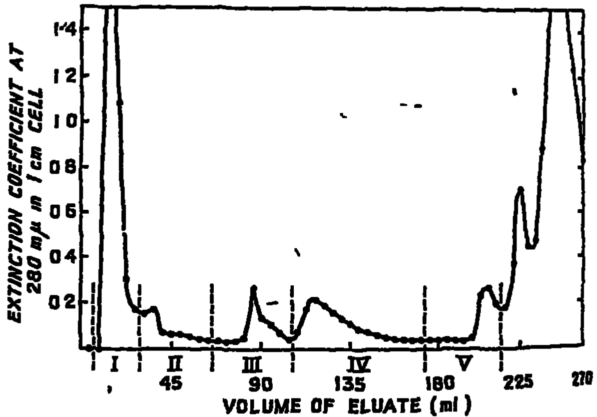

Fig 1—Chromatography of 3 ml human serum on 3 g diethyl amino ethyl cellulose (Column 12 × 1 1 cm)

0–45 ml eluting with 0 01 M sodium phosphate pH 7 5
45–180 ml eluting with 0 02 M sodium phosphate pH 6 2
180–270 ml eluting with 0 05 M sodium dihydrogen phosphate

In fig 2 the results with peaks 1 and 3 are shown

Electroendosmosis has moved both fractions towards the cathode, but it is clear that there is a distinct difference in their mobility Fractions 2, 3, and 4 were indistinguishable by paper electrophoresis Fraction 5 contained material moving between the γ and β bands, and later fractions were complex but contained no γ globulin

Of eight sera examined, all showed similar patterns with the same components present Some quantitative differences were seen in the relative proportions of each

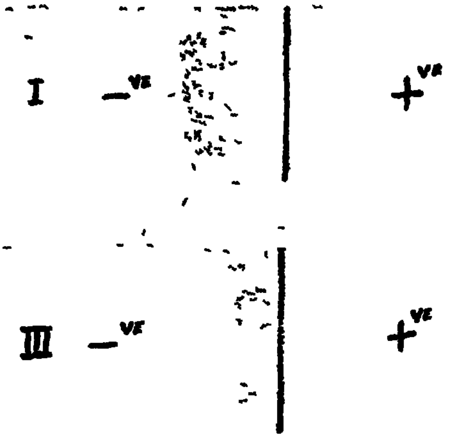

Fig 2—Electrophoresis on paper at pH 8 6 of fractions 1 and 3

TABLE I—REAGIN ACTIVITY OF γ-GLOBULIN FRACTIONS
(Weal area in sq mm with J M serum)

Concentration	Fraction					Whole serum
	1	2	3	4	Euglobulin	
1/1	0	70	100	60	0	90
1/10	0	10	60	trace	0	80
1/100	0	0	trace	0	0	50

fraction but no attempt was made to evaluate these variations

Each fraction was concentrated to the volume of the serum used and then assayed for reagin activity This method of comparison gave the relative total amount of reagin in each fraction but it did not give the activity per milligramme of protein, for the weight of protein in fraction 1 was about two-thirds of the total γ-globulin and hence there was a much higher protein concentration in the test solution

The results of the reagin test with J M serum are given in table I The most striking feature is that fraction 1 is devoid of activity, some is present in fractions 2 and 4, but fraction 3 was by far the most active No activity was detected in the other fractions, nor was any present in the small euglobulin precipitate which formed when the serum was dialysed against 0 01 M buffer before chromatography With four other sera very similar results were obtained, and in some cases activity was found only in fraction 3

TABLE II—REAGIN ACTIVITY OF γ-GLOBULIN FRACTIONS
(Weal area in sq mm, with D A serum)

Concentration	Fraction					Whole serum
	1	2	3	4	5	
1/5	40	36	90	80	40	130
1/25	20	0	40	10	0	60
1/125	0	0	10	0	0	10

The sixth serum (D A), from a person who was very sensitive to horse-serum, gave a somewhat different result The reagin content appeared to be much higher, and the results obtained with the different fractions are shown in table II Activity is more widely distributed and some is present in fraction 1 Fraction 3 has most of the activity and, if judged by activity per milligramme of protein is much the highest, fraction 1 being clearly the lowest. It is possible that the relative distribution of activity here is similar to that in the other sera, but, as the total content is higher, it has now become more apparent in the least active fractions

Serum D A was tested for precipitins against horse-serum by the ring test and by diffusion in agar, but none were detectable

DISCUSSION

This work has confirmed the observations of Kuhns[4] and Brattsen et al[5] that reagins against several antigens are found chiefly in the γ^{1} globulins It has further shown that the reagins are principally in one fraction of the γ^{1} globulins, and this technique would appear to offer a simple method of purifying reagins The significance of restriction of the reagin activity to only about 10% of the total γ globulin fraction is not clear When sera from two "normal" people were chromatographed there was no apparent difference in the elution pattern Neither of these subjects had ever had any known allergic symptoms and they gave negative skin tests to the antigens tested It seems, therefore that fraction 3 is a normal constituent and that only a small part of it is reagin

No human serum with a satisfactory content of precipitins could be obtained, but when a rabbit anti-bovine serum-albumin serum was fractionated by the same technique, there were found to be three principal γ-globulin components and the proportion of antibody in each was the same (within the error of the method) This serum was taken from a hyperimmune rabbit (16 mg precipitating antibody per ml serum) and it is uncertain whether this result has much significance in relation to the results to be expected with a human serum containing precipitin It may perhaps be taken to suggest that human precipitin will be present in most fractions and not sharply localised as are the reagins Using the purified reagins of fraction 3, we were able to confirm that unlike that of precipitins, their activity was destroyed by heating at 56°C for 4 hours as has been reported using whole serum[8] Attempts were made to test for inhibiting or potentiating factors in the other serum fractions by comparing the weal size produced by fraction 3 alone and by fraction 3 mixed with other fractions, but no evidence of any such effect was observed

One possible explanation of these results is that suggested to explain the complexity of rabbit γ globulin[9] Different types of cells perhaps localised in certain tissues produced distinct kinds of γ-globulin Perhaps only a small number are capable of producing reagins; or perhaps the route of entry of the antigen is such that only a small number receive the stimulus Test of this suggestion could perhaps best be made by finding whether certain tissues were able to synthesise only some of the γ-globulin fractions

SUMMARY

When human serum is fractionated by chromatography on diethyl amino ethyl cellulose, the γ-globulin can be resolved into four components The reagin content of serum from allergic subjects is almost confined to one of these components which contains about 10% of the total γ-globulin

We are grateful to the members of the institute staff who gave blood or allowed us to test fractions in their skin The test antigens were kindly given by Dr John Freeman, Inoculation Department, St Mary's Hospital London, and by Major Milner of Bencard Ltd.

We wish to thank Miss J Morgan for her excellent technical assistance

Medical Societies

ROYAL SOCIETY OF MEDICINE

The Nephrotic Syndrome

ADDRESSING the section of pædiatrics of the Royal Society of Medicine on Jan 18, Prof C A JANEWAY, professor of pediatrics at Harvard University, dealt chiefly with his clinic's experience of the nephrotic syndrome in children, in whom it was less variable in its ætiology than it was in adults Before the introduction of antibiotics, they had thought that there were two separate conditions "pure lipoid nephrosis" and "chronic glomerulonephritis with œdema" The lipoid nephrosis most commonly began at the age of 2 or 3 years and 83% of deaths were due to infection, pneumococcal septicæmia being the most frequent Chronic glomerulonephritis with œdema showed a similar age-incidence but only 27% of deaths were due to intercurrent infection; renal failure was responsible for 63% The introduction of antibiotics had completely altered the natural history of the disease Death from infection was now uncommon in most hospitals and clinics Early treatment of infection was very important With the knowledge and consent of the family doctor the parents of nephrotic children were given tetracycline drugs and instructed to begin treatment at the first evidence of infection, and to give prophylactic therapy at half dosage if a respiratory infection appeared in other members of the family Antibiotics had greatly prolonged life but had had little, if any, effect on final recovery About two-thirds of all nephrotic children still died of the disease, but now renal failure was by far the most common cause of death The classical "large white kidney" of the nephrotic syndrome was now a pathological rarity Such kidneys were previously found in children dying early in the disease from pneumococcal infection, but now the kidney at death showed periglomerular scarring with obliteration of nephrons

---

[8] Pappenheimer A M J Immunol 1955, 75 259
[9] Askonas B A Humphrey J H Porter R R Biochem J 1956 63 412

Professor Janeway and his associates now thought that almost all examples of the nephrotic syndrome in children were due to a membranous type of glomerulonephritis, and it was impossible to predict the eventual outcome early in the disease Modern clearance techniques had given valuable information about the disordered physiology of the condition During the first month the glomerular filtration-rate was invariably low but the renal plasma flow was often normal, and therefore the filtration fraction was reduced Thereafter, during the early reversible phase of the disease, clearances were variable and the glomerular filtration-rate sometimes increased above the normal levels, but it often remained low During this stage full recovery was possible even in cases complicated by azotæmia, hypertension, or hæmaturia In the later irreversible phase the low glomerular filtration-rate became progressively reduced until death resulted from uræmia

The work of Professor Janeway's colleague, Dr Gitlin, had shown no evidence of abnormality in the chemical composition of plasma-protein in the nephrotic syndrome Albumin from plasma, urine, œdema fluid, and ascitic fluid was identical with normal plasma albumin when tested by delicate immuno chemical methods The albumin deficiency was partially attributable to increased urinary loss but also to increased metabolic breakdown In contrast, β-lipoprotein, consisting of macromolecules containing 90% lipid, did not pass through the glomerulus and was metabolised at a diminished rate This globulin therefore accumulated in the plasma and accounted for the lipæmia of the nephrotic syndrome Changes in electrolyte metabolism, demonstrated by Metcoff, and consisting of abnormal sodium retention and urinary potassium loss, were thought to be secondary to increased production of aldosterone by the adrenal cortex, which had been detected in the urine by Luetscher This was probably a physiological response to reduction of blood-volume due to lowered colloid osmotic pressure in the plasma Increase of circulating blood volume by salt retention, however, inevitably increased the extracellular fluid volume and thus caused œdema

Diet could not be so strict in the management of the nephrotic syndrome in children as it was in adults Children did not tolerate rigid salt deprivation, and often refused high-protein diets Cortisone and corticotrophin (A C T H) usually caused a satisfactory diuresis unless the patient was in the later irreversible phase of the disease There was inadequate evidence to determine whether the natural history of the nephrotic syndrome was modified by hormone therapy It had still not been finally decided whether treatment with hormones should be intermittent or continuous, but Professor Janeway thought that the balance of evidence was probably in favour of continued treatment until proteinuria had completely disappeared or had become very slight

Little progress had been made in elucidating the cause of the nephrotic syndrome The disease produced in rats by injection of anti rat kidney rabbit serum, as shown by Heymann, was very similar to the condition in man All cases of the nephrotic syndrome, as well as disseminated lupus erythematosus and acute glomerular nephritis, were associated with reduction of serum complement These facts suggested, but did not prove, that the condition might be due to an immuno chemical factor which was as yet completely undefined

Reviews of Books

Diagnosis and Treatment of Peripheral Vascular Disorders

DAVID I ABRAMSON, M D , F A C P , professor and head of the department of physical medicine and rehabilitation, and professor of medicine, University of Illinois, College of Medicine London Cassell 1956 Pp 537 5 guineas

THIS book is not designed for the specialist in peripheral vascular disease, but it does offer in a very palatable form basic anatomical and physiological data concerning the peripheral vessels, the signs and symptoms associated with their disease, and some of the problems in differential diagnosis The text, written by a physician with physiological leanings, is concise, lucid, and well illustrated In the text medical therapy prevails to the virtual exclusion of surgical measures Many readers will regret that the scope and indications for surgery are not indicated more fully, as doubtless some physicians find difficulty in selecting patients to refer to a vascular centre With this reservation the work can be warmly recommended for the general physician or practitioner

The Complete Cookery Book for Diabetics

IRIS HOLLAND ROGERS London H K Lewis 1956 Pp 110 5s

THIS little book will be an eye-opener to many diabetics and those that cook for them, for there is enough variety in the numerous recipes given to destroy the monotony of the unnecessarily rigid diets followed by many diabetics

The carbohydrate, protein, and fat content of each dish is given so that it is still possible (invoking, it must be admitted, a modicum of intelligence) to keep the food value of the diet constant But achievement of this desirable goal is somewhat impeded by a slight defect in the book a number of 10 g carbohydrate exchange dishes are described under the heading of savouries but no attention is drawn to their content of fat and protein There is a good section on invalid meals designed to provide carbohydrate in easily assimilated form during intercurrent illnesses, and a useful table giving the weights and equivalent household measures of common foods Sorbitol is widely employed, especially for sweets, cakes, and preserves In some of these it could not be replaced by saccharin, but it has the disadvantage of being too expensive for some diabetics and of having some carbohydrate value, although it is assumed to have none in these recipes Many diabetics would prefer to use weighed amounts of cane sugar instead, even if they were allowed smaller portions of the foods thus prepared

Nevertheless this book is undoubtedly valuable

Clinical Hematology (4th ed London Henry Kimpton 1956 Pp 1185 £5 12s 6d)—The latest edition of Prof Maxwell M Wintrobe's work fully maintains its place as the premier hæmatological textbook Professor Wintrobe takes pains to emphasise that history taking, clinical examination, and study of the patient are essential, hæmatology cannot be effectively practised in the laboratory alone The changes in the five years since the last edition have made necessary new chapters on blood groups, blood transfusions, and syndromes associated with abnormal hæmoglobins The chapters on hæmorrhagic diseases, hæmolytic anæmias, and the production and destruction of red blood cells have been almost entirely rewritten Extensive revision is evident everywhere, and in the bibliography—a valuable asset—1600 references have been added and 887 deleted Therapy has been brought fully up to date This book is a sane appreciation of the present state of hæmatology, and the new edition will be needed by all who practise the specialty

THE LANCET

LONDON SATURDAY, JAN 26, 1957

Nurse and Doctor

No-one who has followed the brisk exchange in our correspondence columns during the past few weeks can doubt that sharp differences have developed between the medical and nursing sides of hospital staffs concerning the recruitment and training of nurses and the proper relation of nurse to doctor Nor can it be doubted that these differences must be resolved if our hospitals are to go on giving good service

The Royal College of Nursing plans to rely eventually on assistant nurses to do the bulk of the practical work, and on a group selected at the start (some of whom would take a degree course) to provide leadership[1] This plan has merits In the first place, the training of the ordinary nurses would be more realistic than that of the S R N at present Secondly, these "assistant ' nurses would be a relatively stable element, and accordingly students would be relieved of some of the routine work that now may overshadow their training (The chief medical officer of the Ministry of Health has lately declared "Too many hospitals still rely on student nurses for too high a proportion of their nursing services "[2]) The scheme would also bring to an end the damaging anomaly that in hospitals where nurses are trained for the State register the patients may be in danger of getting too little nursing attention owing to the trainees preoccupation with their studies and the rule that assistant nurses in training may not be employed in the same wards But the whole plan would founder without recruitment of "assistant" nurses in large numbers and this the arrangements so far proposed do not ensure

The college may hope to increase recruitment of "assistant ' nurses by its proposal to increase the number of training-schools for them. But this measure alone will not convince ' assistant " nurses that they are not pursuing a second-best course The very word ' assistant implies that they will be taking second place to nurses proper If they are to do most of the practical work this title will be even more misleading than it is now, and it will continue to damage recruitment The G.N C should overcome its hesitations and give these people the title they deserve—namely nurse—finding other names for other groups Furthermore, these nurses should be assured that if they show merit they can make the leap into the leaders group Such a provision is essential not only because many are reluctant to start on a career in which there is no hope of progress, but because thereby the stock of leaders may be usefully enriched the good practical nurse of 18 may emerge as an able administrator at 21 Indeed, can leaders be confidently selected at 18? Experience with candidates for other callings has encouraged no great confidence in selection methods, and such methods (as Dr **Fourman**[3] remarks) must be especially hard to apply in a vocational profession We still believe—as we believed twelve years ago[4]—that the choice of most of the leaders would best be deferred until basic training is completed. Besides encouraging recruitment of ' assistant ' nurses and easing the choice of leaders this might help to preserve the unity of the profession The offer of a different kind of training from the outset may attract to nursing some people with lively minds who otherwise would turn to other work but any such gain may be offset by the isolation of the selected group from the practical nurses who from the start follow a different course The unhappy effects of such isolation are evident in the United States, where university training has been carried much further than in this country At present nobody knows whether leaders are best chosen before or after basic training or by other methods including recruitment among older people, some of whom may have already graduated in arts or sciences at a university[4a] and therefore meanwhile no one method should be followed to the exclusion of others

Now some nurses, vigilant for their professional independence question the doctor s right to be heard on these questions 'It is surprising,' writes one correspondent[5] that doctors should consider themselves in a position to criticise nurse-education Many nurses could make pertinent criticisms of medical education, except that they do not consider they have any right to do so' This overlooks the fact that the quality of hospital medical care depends largely on nursing skill doctors cannot possibly remain indifferent to the way in which nurses are recruited and trained The same correspondent writes ' Nursing in the sense of caring for the sick, can be quite independent of medical care it can be good, bad or indifferent, so that the patient can be well treated medically but inadequately nursed Similarly, the patient can be well nursed but inadequately treated ' True, but where such division is manifest the patient is badly cared for In the best hospital practice the nurse is the agent of the doctor in much of her work Who shall say that the nurse keeping a fluid-balance chart, or recording a blood-pressure, or tending a patient recovering from anæsthesia is practising a nursing rather than a medical technique ' And it is these very tasks—so often difficult and requiring much skill—that largely justify the recruitment of gifted people to nursing and the continuing growth of the profession s prestige Dr **Anderson**[6] doubtless with such tasks in mind, wrote that nursing should develop along the lines of the needs of the doctor and of the public "whom we both serve This drew from a senior nurse[7] the retort that "the nurse renders her service to the patient, not to the doctor"—a thought which, if carried far enough, would deny the nurse much of her most interesting and most rewarding work and would bring the routine of acute wards to a halt More than one medical correspondent[8] [9] has pointed out that a dangerous alternative to continued integration of medical and nursing work is the establishment of parallel services in which the nurses would communicate with the doctors (in Dr **Ritchie Russell**'s words[8]) "only through carefully delineated channels" In the ward, parallel services should have no place, because one person must take final responsibility the care of patients cannot be conducted by committee Such responsibility should, as hitherto, be vested in the clinician, and this arrangement, dictated by necessity, subordinates the nurse to the doctor no more than the hospital biochemist or physicist is subordinated to the doctor Both doctor and nurse must wish to work towards easing tensions in their old and unbreakable alliance The doctor's relation to the nurse differs from his relation to any other of the medical team To the physiotherapist and the almoner, for instance, he turns intermittently, but to the nurse (as Miss **Edwards** remarks in her letter on p 217) he looks for continuous and intimate help Her eyes and ears, and many of her techniques, are extensions of his own In hospital the doctor cannot work properly without the nurse's close support, nor can the nurse without the doctor's It would be folly for either to pretend otherwise

Ménière's Disease

It is nearly a hundred years since **Prosper Ménière** described the condition which bears his name and related the symptoms to disturbed labyrinthine function As far as clinical description is concerned, little has been added since Classically, attacks of rotatory vertigo, often accompanied by vomiting, are heralded by increasing tinnitus and deafness As the attack subsides, the tinnitus tends to become less prominent, but the hearing gradually or quickly deteriorates with each successive attack Distortion of sound, which is a special feature of Ménière's disease, reduces still further the patient's ability to use his residual hearing Psychological disturbances are common, and this is not surprising in patients who are ever expecting further attacks of disabling giddiness It has therefore been said, with some justification, that any treatment applied with sympathetic interest is likely to be helpful[10] This fact, and the natural tendency to remissions of up to several years, combine to make the assessment of any treatment a long and difficult task

Elucidation of the pathological basis of Ménière's disease has lagged a long way behind its clinical recognition, because opportunities for post-mortem studies were few, and even those examinations that were possible were made technically difficult by the ivory-hard bone surrounding the internal ear It was not until 1938 that **Hallpike** and **Cairns**[11] demonstrated that the essential lesion is a dilatation of the endolymphatic system, accompanied by a degeneration of the sensitive cochlear and vestibular end-organs They suggested that the sudden attacks of vertigo began when the endolymphatic pressure rose to the critical point at which the blood-vessels were obliterated, and the resultant ischæmia paralysed the end-organ Since then, hydrops of the labyrinth has often been confirmed as the lesion of Ménière's disease, but the mechanism of this accumulation of endolymphatic fluid has not yet been satisfactorily explained Among the many hypotheses put forward, vasomotor disturbances in the internal ear have commanded most interest in recent years an allergic vascular spasm,[12] a Raynaud-like mechanism,[13] and autonomic imbalance[14] are among the most acceptable The autonomic nervous system has no direct influence on the organs of hearing and balance, but stimulation of the sympathetic trunk in cats can reduce the blood-flow through the spiral ligament[15] The endolymph is produced more slowly after sympathetic stimulation and it is altered in character, so that later the endolymphatic pressure rises as a result of osmotic exchanges **Lewis**[16] believes that there is some primary fault within the labyrinth, which produces its effects by way of the vascular supply to the internal ear Sympathectomy, by its action on the blood vessels, modifies the course of the disease without affecting the primary cause

Medical treatment is often successful The use of sedatives or anti-histamine preparations aims at reducing the immediate symptoms until the organism has had a chance to readjust the endolymphatic balance Fairly large doses of vasodilator drugs, such as nicotinic acid, may help the patient to achieve this balance more quickly and to maintain it, and they have enabled up to 90% of patients to return to and remain at work[17] But for those patients who do not promptly respond to conservative treatment, and who have only a distorted and useless remnant of hearing, surgical destruction of the diseased labyrinth offers the surest escape from the demoralising attacks of vertigo, with their dangers to life, limb, and livelihood[10]

There remains a small, difficult, but interesting group in which surgery is required because medical treatment has failed, but in which it is important not to destroy the hearing in one ear The indications for such conservative surgery have recently been set out by **Harrison**[18] in patients with unilateral disease, a conservative operation may be considered for those with good hearing in the affected ear and those whose hearing on the opposite side is reduced by some other cause, and when the disease is bilateral, it is always desirable to halt the loss of hearing as well as the vertigo But the chief defect of all the conservative operations is the uncertainty of preserving the hearing while abolishing the vertigo **Portmann**'s operation[19] of draining the saccus endolymphaticus has been used intermittently since 1927 Logical though the method seems, the results have seldom been satisfactory **Flett**[20] says the operation offers a 25% chance of retaining the hearing and relieving the vertigo and tinnitus, and a 60% chance of relieving vertigo but with a gradual loss of hearing. Limited operations on the vestibular labyrinth[18] seldom succeed, since any sort of intralabyrinthine instrumentation in Menière's disease usually leads to complete loss of both cochlear and vestibular function. If some function is retained, both the cochlear and vestibular elements may well continue their disordered action as they did before the operation. The intracranial division of the vestibular portion of the 8th nerve is a major operation, but in most cases reported in this country[10] and elsewhere the patient has retained his hearing. It is undertaken in bilateral disease to salvage the better-hearing ear, and in some unilateral cases with good hearing. Destruction of vestibular function without operation has been achieved with streptomycin. Unfortunately both sides are affected, making the treatment most suitable for the younger patient with bilateral disease—an unusual combination. To offset the total loss of vestibular function calls for considerable adaptation which the elderly find very hard to achieve and the resulting incapacity may be greater than before.[21] The drug may also damage further the already declining hearing, and a very careful check must therefore be kept on the state of the hearing. Any further deterioration means that the streptomycin must be stopped at once. The vestibule has also been successfully destroyed on one side by ultrasonic rays,[22] but in this country the efficacy of this method has not yet been assessed.

Cervico dorsal sympathectomy is a method of treatment of which more has been heard lately. LEWIS[16] and HARRISON[18] found that injection of the stellate ganglion was not a success either in treating the attacks of giddiness or in selecting cases for operation. On the whole, patients with unilateral disease did better after sympathectomy than those with both ears involved, probably because the disease is usually more severe when both ears are affected. It is interesting that the improvement or disappearance of the vertigo was sometimes delayed for up to a month after the operation. Many of their patients have had no further loss of hearing over the course of several years, and the operation is probably effective in preventing or retarding the progression of the deafness. The place of sympathectomy in the treatment of Menière's disease, however, seems to be limited to those few patients in whom the disease is bilateral and the deafness progressing in spite of medical treatment. Early operation may preserve the hearing but improvement of hearing after late operation is rare.

Pressure and Flow in Arteries

THE formula devised by FRANK[23] expressed the relationship between arterial pressure and flow as resistance, and measured it in the specific terms of dynes per cm^{-5} per second. This is a convenient single expression connecting pressure and flow but it is almost certainly not a valid measure of the peripheral resistance of the cardiovascular system. FRANK's formula is based on Poiseuille's law which was intended to define the relationship between pressure and flow of an ideal liquid passing steadily through a rigid tube of uniform calibre. But in the mammalian circulation a pulsating stream of a complex suspension flows through elastic tubes, with changes of velocity and cross-sectional area at each subdivision of the network. The relation of pressure to flow must therefore be clarified before FRANK's formula can be applied to the circulation in anything but a casual way. The ultimate aim of many inquiries into pressure and flow has been to measure cardiac output from an aortic or arterial pressure tracing, and with this object in view the arterial system as a whole has been investigated. Eventually HAMILTON and REMINGTON[24] put forward an empirical formula which related various parts of the aortic pulse contour to the volume of the blood ejected from the heart. The formula gave a reasonable prediction of the cardiac output of the dog under specified conditions but it failed to do so when the conditions were altered.[25] This and other careful investigations have made it clear that our present views on hæmodynamics cannot fully explain the pressure and flow changes observed in the animal circulation as a whole.

It seems that progress will be faster if the complex problem can be broken down into its constituent parts. COULTER and PAPPENHEIMER[26] studied the seemingly straightforward matter of the physical properties of blood flowing along a tube, and, as might have been feared, these turned out to be far from simple. Though the "viscosity" of blood may be measured, the measurement has meaning only if it is made under conditions which are closely and clearly defined. When blood flows along a tube, the corpuscles flow in an axial stream and the viscosity of the blood varies with the velocity of the stream and the area of cross section of the tube. When the velocity is great, as in the aorta during systole, turbulence develops[27] and the effective viscosity of the blood is much increased. These findings upset the simpler ideas of blood viscosity: for example, it is usually held that viscosity must be increased when the red-cell count rises, but this is true in only a limited sense, for PAPPENHEIMER has shown that at high velocities of flow the effective viscosity of polycythæmic blood may be less than that of normal blood, because the increased mass of the corpuscles tends to stabilise the stream and make turbulence less likely. The problem has also been simplified by investigating only a part of the circulation. LANDIS[28] measured pressure, diameter, length, and rate of flow in the arterioles and capillaries of the frog's mesentery, and GREEN et al.[29] studied the connection between mean pressure and flow in the perfused hind leg of the dog. Both inquiries made it plain that many adjustments were needed before the observations could be combined in a relationship based on Poiseuille's law. PETERSON[30] injected a known volume of blood into the aorta of a dog at selected instants during the pulse cycle, and showed that equal injections did not cause identical or even predictable superimpositions on the pressure pulse curve In his view, the systolic force needed to impart linear acceleration to the blood-mass in the arterial tree is an important consideration in pressure flow changes within the aorta McDonald[27] and Womersley[31] have re-examined pressure and flow in the dog's femoral artery under standard conditions They measured the changes of pressure gradient between two points along the artery, and the coincident changes in blood-flow velocity were recorded by means of high-speed photographs of an oxygen bubble in the artery They found that the oscillating pressure-gradient was related to the volume-flow which it generated after a time lag, in rather the same way that an alternating voltage is related to the corresponding current In fact, Womersley has devised an "alternating-current" theory of flow, to be distinguished from the relationship based on Poiseuille's law (which can be considered as the "direct-current" theory) According to the "direct" theory, it may be permissible to think and speak of the sum of the resistances of the branches of a network of vessels, but when there is an oscillating pressure in a branching system it would be more correct to consider the effect of branching as analogous to a sum of impedances Using the "alternating' theory of flow and the standard principles of hydrodynamics, the flow to be expected over a known pressure-gradient in the femoral artery was calculated, and the agreement between the observed and calculated volume of flow was within the limits of observation error Thus, the theory seems to have been justified

Observations by Burch[32] encourage the hope that similar fundamental work may be possible in man, using relatively simple methods Burch used venous-occlusion plethysmography to measure the phasic changes of blood-flow in the finger The finger-tip is enclosed in an airtight rigid container which does not obstruct the circulation When the venous outflow is briefly occluded by a pressure cuff on the finger, the volume distal to the cuff increases by the amount of blood flowing into it during the period of occlusion, and equal volumes of air are displaced to and from the plethysmograph into a continuous recording system Until now it has been customary to measure the mean rate of blood-flow over a brief period, though the original description of the plethysmographic method by Hewlett and Van Zwaluwenburg[33] was much concerned with observations of the phasic changes in the rate of flow Burch has adapted the finger plethysmograph to record the rapid changes of flow into the finger during the phases of the pulse cycle To this technique he has given the cumbersome name of electro-rheoplethysmography, but perhaps the title is justified since he observes the time-course of the volume changes, the rate and acceleration of inflow and outflow, and the difference between inflow and outflow of a single pulse cycle Tracings are taken from two fingers simultaneously, and the venous outflow of one is intermittently occluded, the other serving as a control for spontaneous changes in the finger-volume The rate of volume-change can then be measured over any portion of the pulse cycle The first derivative of the volume-time chart gives the time-course of the inflow and outflow rate, and the second derivative the acceleration-rate of the blood inflow The form of such curves has yet to be related to the form of the arterial and venous pressure pulses They vary considerably in different physiological and clinical states, and the study of these changes is likely to further our knowledge of the function of the central and peripheral circulation in health and disease

But it is doubtful whether the finger-tip is the most suitable part in which to study the circulation The smaller vessels of the digits are specialised to take part in the control of body-temperature, and they are particularly rich in arteriovenous anastomoses,[34] which are readily opened and shut by thermal and nervous stimuli For this reason blood-flow fluctuates widely in the finger-tips, and it might also be expected that there would be an unusual range of pressure gradient between the arterial and venous ends of the capillaries Observations on these vessels, therefore, cannot be interpreted as typical of the circulation as a whole Furthermore, plethysmographic records from the finger-tips may be unsatisfactory for technical reasons The part of the inflow curve from which reliable readings may be made is limited by the artefacts caused by the inflation of the cuff at the beginning of the curve and by venous congestion at the end When the vessels are dilated and the arteriovenous anastomoses widely open, the artefacts may so approach each other that no reliable estimation of the blood flow can be made Burch considers possible methods of dealing with these limitations, but his suggestions are not entirely convincing, and the forearm or calf might be a better part of the anatomy to investigate

These important and interesting investigations bristle with technical difficulties Electromanometers are not hard to find, so that the recording of phasic pressure changes in the cardiovascular system is relatively simple, but the simultaneous recording of phasic flow changes is a different matter Improved methods, however, will probably simplify the present abstruse picture of pressure and flow Meanwhile, there should be no serious objection to expressing the relationship between mean pressures and mean flow in terms of "peripheral resistance," so long as it is clear that the term is no more than an arithmetical arrangement of pressure and flow measurements, and that a change of "peripheral resistance" does not necessarily denote a change of calibre of arterioles or "resistance vessels"

The New Minister of Health

Mr Dennis Vosper has been appointed Minister of Health in Mr Macmillan's Government

Mr Vosper, who is 41, was educated at Marlborough College and Pembroke College, Cambridge During the late war he served with the Cheshire Regiment and held the rank of major He was returned to Parliament as member for the Runcorn division of Cheshire in 1950, and the following year he became a Lord Commissioner of the Treasury From 1950 to 1954 he was a whip As parliamentary secretary to the Ministry of Education since 1954 he has taken a special interest in the welfare of handicapped children

Mr J K Vaughan-Morgan, who has represented Reigate since 1950, has been appointed parliamentary secretary to the ministry He has been chairman of the Conservative health committee

Annotations

SAVING THE POTENTIAL SUICIDE

"O Britain infamous for suicide!" wrote the Rev Edward Young[1] in 1742, and he might still thus apostrophise our nation As Dr Parnell and Dr Skottowe observe in their article on p 206, the Registrar-General recorded, in 1954, in England and Wales, 5043 suicides—which represented an increase of nearly 50% in ten years In Britain today, more people commit suicide than are killed on the roads Of the 100 suicides about which they gathered information, Parnell and Skottowe found that in 53 the victim had not recently been under medical care But in the majority there had been warning signs, of which a change of mood, with noticeable depression, was the commonest As Parnell and Skottowe see it, the best chance of saving the man or woman with thoughts of suicide is admission to a mental hospital for supervision and treatment but they acknowledge the difficulties of convincing not only the patients but their families and the general public of the importance of this precautionary measure

From the general practitioner's viewpoint depression is so common a symptom that it is often hard to pick out the patient who is heading for disaster In ten years Watts[2] saw 387 patients with endogenous depressions, including 6 who committed and 8 who attempted suicide, 3 of those who killed themselves were not under medical care at the time As Craddock[3] has pointed out, it is all too easy to overlook endogenous depression, for, like cancer and tuberculosis, it usually comes on insidiously Oliven,[4] among others, has offered useful advice to the family doctor who must decide whether or not a patient is in danger of suicide In his view, even vague or minor signs of depression, and its concomitants, such as insomnia, loss of appetite, and libido, and abnormal fatigability, should be taken as danger signals, though the greatest care will never save the occasional patient who commits suicide without warning More could perhaps be done by reminding the public that depression is a reason for seeking medical advice And certainly, as Parnell and Skottowe emphasise, doctors must be less chary of asking frank questions about how depressed the patient is and whether he has any suicidal intentions The depressed patient more often escapes notice than the psychopath, the schizophrenic, or the alcoholic, and "that a patient does not threaten suicide, or again that he speaks logically, is no excuse for inaction"

But the best answer may lie further back—in a livelier awareness, among public and profession, of what can be done by the preventive measures of social psychiatry and psychotherapy[5] A world of unstable international and national conditions and loss of faith may favour despair in people who are not so stuffed with bread and circuses that they doze through their waking hours The man who says "I couldn't care less" may be closer than he knows to taking an action which will relieve him of the need to care any more about anything Another even more depressing view is that the importance of the individual and his welfare has been so overplayed in some countries that the will to struggle for life and livelihood has been lessened, and will not be restored until the cushion of the Welfare State is made a bit harder However that may be, it is, in the first place, to preventive psychiatry that we must turn for real help in reducing the number of suicides and in enabling those that are saved to find stability, even in an unstable world

FAILURE OF ARTERIAL GRAFTS

THE commonest site for advanced degenerative disease of peripheral arteries is at the junction of the femoral and popliteal arteries, and from here the clot spreads upwards or downwards It is unfortunately quite clear that the results of direct vascular surgery have been very unsatisfactory in these limb vessels, and the causes of early and late failures in grafting are therefore of the greatest interest Several possible causes demand attention First, the surgeon may be technically at fault by creating a stricture at the anastomosis between the graft and host artery, so that thrombosis inevitably follows That this is of great importance is suggested by the superior results of grafting when big vessels such as the aorta or iliacs are involved It is equally certain that the use of small vessels, such as the posterior tibial, for the distal anastomosis is followed by a 100% thrombosis rate Other technical faults are the lifting and loosening of athero matous plaques by the needle point or the leaving of too much free silk within the lumen in contact with the bloodstream Because of the larger lumen which can be fashioned, the end-to side type of anastomosis is less likely to thrombose than the end-to-end type The kind of graft which is most suitable for peripheral arteries is still a matter for debate Free vein grafts, homologous arteries, and tubes of synthetic fibres all have their supporters of the man-made fibres, polyvinyl alcohol seems most promising The benefits of crimping the graft to make it flexible without kinking have been shown in vivo to be short lived because the invading connective tissue rapidly converts it into a smooth semi rigid structure

Szilagyi et al.[1] have confirmed some of the earlier reports of degeneration, thrombosis, calcification, and aneurysm formation following the use of homologous arterial implants The problem of homograft degeneration is a difficult one, and data regarding the source of the grafts and their processing or storage do not help The way in which host tissues vary in their acceptance of homografts of grossly similar characteristics suggests that the host-graft reaction may be an immunological one[1]

The factor which has most to do with success or failure may be the selection of the patients There is no doubt that results of grafting for traumatic or congenital lesions of arteries are much more satisfactory than those of operations undertaken for arteriosclerosis, and, in the arteriosclerosis group, vessels with relatively localised segmental thromboses do much better than those in which the narrowing involves the whole tree Furthermore, the degeneration is progressive and the relief of a localised thrombosis is often followed by further lesions elsewhere in the leg

Szilagyi et al[1] reviewed their experience with 120 homograft operations for aorto iliac or femoro popliteal occlusions In 23 there was clotting immediately after the operation During the next thirty three months, 21 more grafts failed to transmit blood 7 of these were re explored and studied clinically or histologically Szilagyi et al concluded that the most common cause of late graft failure was the extent and severity of the preexisting arterial disease Occlusions due to defects in the homografts which developed after their implantation were uncommon, but there was often progressive narrowing or unevenness in the follow-up angiograms and this might lead to eventual obstruction Szilagyi et al's paper was read before the American Surgical Association, and from the discussion which followed it was clear that many surgeons were uneasy about the results of small-vessel grafting The proportion of late closures in the region of the femoral artery was as high as 70% The variation in failure-rate reflects differences in the original selection of patients and indeed illustrates the outstanding clinical problem for the vascular surgeon Should he select only those patients with early disease and moderately severe symptoms in whom the results of grafting are fair or should he reserve direct surgery for very advanced disease, in which the results are in general poor but occasionally dramatic[9]

AUSTERITY DIETS

THE National Food Survey has been in being since July, 1940 Year by year it has recorded the food consumed in many thousands of households, and analyses of these data enable some assessment to be made of how the food consumption of the people measures up to accepted standards of physiological needs The Survey's findings were of great value to the Ministry of Food in planning and coordinating its policy during the late war and immediately afterwards, when food was scarce During those years the staff of the Ministry had not the time to analyse fully the mass of data available and to present the results in a scientific report When the pressure of the times became less heavy, the Ministry concentrated very wisely, on the preparation of up-to-date annual reports, of which the first to be published was for 1950, but a report was also prepared which gave some account of the trends in the earlier years A second report[1] now issued presents a large selection of the information available for the years 1944–49 It was not possible to fulfil the original programme which included the earlier years—for one thing, old punched cards get worn and unusable—but the new report does cover the period when food was most scarce and the rationing system most strict, it is an important historical document describing household diets when the war-time system of controls was in full operation The pre-war free economy, with much unemployment and social inequality, had been replaced by a controlled economy, with strict rationing of basic food, and by full employment

It is at once apparent from the report that this change had profoundly altered food consumption Boyd Orr demonstrated that in the pre-war years about 10% of the population (that is some 4 million people) were living on diets which were deficient in both quantity and quality, and this estimate has never been seriously challenged Yet, in the years 1944–49, no section of the community was eating a diet which fell significantly short of the standards set by the British Medical Association Higher wages enabled the working man to buy for his family a better diet, but for the middle classes there was a real reduction in the variety and palatability of their food The country's food, though wholesome and nutritionally adequate, was dull

The report tries to determine how the diet was affected by various circumstances One chapter records details from families who were badly housed, but it turns out that their diets differed surprisingly little from those consumed in other working-class homes Another chapter shows that family size determines the quality of the diet far more than the occupation of the parent The amount of milk, meat, vegetables, and fruit consumed was significantly less in families with four or more children and in this group the protein intake was below the B M A recommendation in all groups of working-class families

Separate analyses are given for the households of agricultural workers, miners, builders, metal workers, and ship builders, but the differences are remarkably small Of more interest is the analysis of the regional differences Less fruit, vegetables, fish, rationed meat, and eggs were eaten in Scotland than in any other part of the country, but the Scottish consumption of cakes, buns, and scones was 12% above the national average The Scots spent only $^1/_{10}d$ a head per week on coffee, whereas the English spent a $^1/_2d$ In England, most cheese was eaten in the Midlands, most fruit in London, most potatoes in the South-West, and most cereals in the North East It might be interesting to try to relate these variations to the incidence of degenerative disease For those concerned with atheroma, it is perhaps unfortunate that fat consumption in the home seems to have been remarkably uniform and almost independent of social class, occupation of wage earner, number of children, or region

The committee responsible for this report have presented skilfully, clearly, and concisely a large amount of information, to which many research workers, among others, will turn with interest

CONSTRICTIVE PERICARDITIS

THE diagnosis of constrictive pericarditis is seldom difficult, if the possibility of the condition is borne in mind and if special investigations are carried out to confirm the diagnosis in atypical cases No age is immune and, though many patients are under 40, older patients may have constrictive pericarditis which may be misdiagnosed as ischæmic heart disease The cardinal symptoms are shortness of breath on exertion, swelling of the ankles, and distension of the abdomen, the cardinal signs, found in almost every patient, are a raised jugular venous pressure and an enlarged liver Often there are a pleural effusion, ascites, a paradoxical pulse, a loud third heart sound, and a reduced pulse pressure but these are not essential to the diagnosis In half the patients the heart size is normal on fluoroscopy, and the remainder have only slight or moderate cardiac enlargement Usually the cardiac pulsation is diminished, but in a quarter of the cases the radiologist reports that movement is not restricted, even though he knows the diagnosis and it has been confirmed by other means[1] Calcification of the pericardium is a helpful finding but it is seen in only about half the cases, even when tomography is used The electrocardiogram is always abnormal but never characteristic. There is usually flattening or inversion of the T waves, and three quarters of the tracings show wide or notched P waves, which closely resemble the P mitrale of mitral stenosis[1]

Cardiac catheterisation is invaluable in confirming the diagnosis and also in assessing the degree of cardiac embarrassment in the rare symptom free patient who is found by chance to have a calcified pericardium The characteristic findings are a raised end diastolic right ventricular pressure, an early diastolic dip and plateau pattern in the right ventricular pressure tracing, and (depending on the degree of left ventricular involvement) a raised pulmonary capillary pressure[1]

The disease is progressive, and once there are symptoms operation is indicated The operative mortality is 10–15%, but better results may be expected as surgical techniques improve and patients are operated on at an earlier stage, before the onset of auricular fibrillation and severe liver damage Recurrences are common (of 78 patients, 11 required more than one operation[1]) but the need for second or third operations will cease when wider incisions are used, to allow of a more extensive pericardectomy, and when anti-tuberculous drugs an

given in adequate amounts for an adequate period[2] Bigelow[3] and his associates recommend a trans-sternal approach with both sides of the chest open All the pericardium over the left and right ventricles is removed, including that over the apex and diaphragmatic surface The phrenic nerves are dissected out and the pericardium posterior to them removed Such a wide exposure allows the venæ cavæ to be cleared and permits speedy repair of the myocardium if the heart is inadvertently opened Bigelow keeps his patients on digitalis in the belief that this prevents postoperative myocardial dilatation Further improvement can be expected for several months after pericardectomy, and the Canadian workers report that venous filling pressures have continued to drop for up to a year after operation

RICHARD PFEIFFER

Koch, Ehrlich, Behring, Gaffky, Loeffler, Carl Fraenkel, Wassermann, Frosch, Wernicke, Kolle, and Richard Pfeiffer—those were some of the staff of the Institute of Hygiene of the University of Berlin in 1887 It is unlikely that so many men of ability have ever pursued the same end with so much vigour under the same roof The games in Valhalla are traditionally hearty, and, knowing German habits in scientific debate, one can be pretty certain that discussion sometimes passed the limits of ordinary politeness It was the golden age of Germany and of bacteriology, and it is characteristic of the purposeful vigour of the times that a thesis on the bacteriology of water was considered grounds for seconding Pfeiffer, an army surgeon of 29, to the institute The choice was wise and from it stem two lines of inquiry which are still productive Pfeiffer's bacillus (which we now call *Hæmophilus influenzæ*) has been dethroned from its place as the "cause" of influenza, but, as Sir Paul Fildes points out in an account[4] of Pfeiffer's life, his observations on the fractions of whole blood necessary for the growth of this organism were the first steps in the path which Fildes has himself trodden—with much distinction Pfeiffer was, in fact, the father of the study of bacterial nutrition, but in those years at the Institute of Hygiene in Berlin his most famous work was probably the demonstration of the "Pfeiffer phenomenon"—the lysis of cholera vibrios injected into the peritoneal cavity of an immunised guineapig Like most of the fundamental observations at that time, this was made in the course of experiments designed to solve a problem of practical hygiene The administrative measures recommended by Koch to combat an epidemic of cholera in Hamburg in 1892 were founded on the assumption that the disease was due to *Vibrio choleræ* The discovery of saprophytic vibrios in many places gave an urgent need for a method by which these might be distinguished from *V choleræ* Pfeiffer showed this could be done by cross immunity experiments in guineapigs *V choleræ* injected into the normal animal multiplied freely in an animal immunised with the same organism the vibrios swelled and vanished In the presence of immune serum the same thing happened in vitro—as readily with the typhoid bacillus as with the cholera vibrio It was indeed the "crowning mercy" in the long debate on the relative parts played by cellular and humoral defences in overcoming infection Pfeiffer followed several lines of inquiry from this original observation and most of them have been fruitful in his hands or in those of others Immunology had arrived

Pfeiffer assisted Koch in his investigations into plague in India and malaria in Italy He obtained the chair of hygiene and bacteriology at Konigsberg and later at Breslau, where he remained until his retirement in 1926 Shortly before the late war he moved to a small watering-place in the neighbourhood He was still co-editor of the *Zentralblatt fur Bakteriologie*, he read avidly, he played the piano and tended his garden He was surrounded by devoted friends and the war was far away In 1945 Silesia was occupied by the Russians Pfeiffer could not or would not leave, and he died in September, 1945, cared for by an old maidservant It was only recently, however, that this was known for certain by his friends in the West So passed almost the last survivor of the heroic age of bacteriology, a man whose contributions to knowledge have benefited the whole world of learning

SEPSIS IN THE NEWBORN

SEPSIS neonatorum can be troublesome in most maternity hospitals and departments and anything that reduces its incidence is worth considering Commonly the primary infection is in the skin and Bruce[1] has carefully investigated the incidence of soreness and sepsis in the skin in a group of newborn children bathed in the usual way, and compared it with the findings in a group in which a semi-dry technique was used (only the face and napkin area were cleaned, with dilute (1 in 500) cetrimide) She found that the differences between the two groups were not significant, but, because it saved labour, lessened handling by the nurses, and allowed the baby to spend more time by its mother, the non-bathing technique was introduced into the hospital as a routine

Though the investigation was very carefully controlled, it was not conclusive as far as sepsis is concerned, since two important features in the natural history of the disease were not considered Firstly, the incidence is irregular There are periods of many months when infection is quiescent few babies are affected and the lesions are mild, then quite suddenly an outbreak flares up with widespread infection and severe lesions, reaching a peak and subsiding within a month or so Secondly, the clinical manifestations are not confined to the period spent in the maternity department A relatively small skin lesion appearing in the first week may heal rapidly and all is thought to be well, but there may be a smouldering focus of infection or perhaps a bacteræmia which bursts out again with septicæmia and a "fixation" abscess in bone or lung as much as sixteen weeks later These cases, by far the most important, appear in the pædiatric wards, and on inquiry it is common to find that almost all the children were born in hospital even in an area where half the babies are delivered at home

Bruce conducted her investigation in a hospital where there are some 2000 deliveries a year, and it covered a period of four months, with 160 and 129 infants in the two groups An investigation lasting two years and including about 1000 infants in each group would have been more conclusive because there would probably have been at least one flare up in that time The observations were limited to the lying-in period, presumably fourteen days or less, a follow up of four months might have revealed some sepsis later

MEDICAL EDUCATION

WE have already mentioned[2] a conference called by the Royal College of Physicians of London on Nov 23 to consider the formation of some permanent organisation for discussing problems of medical education, for exchanging information, and for further research The college's initiative was welcomed by the conference, most of whose 69 members came from teaching schools and licensing bodies, and a steering committee was appointed to report on the possible form and scope of such an organisation This is to meet shortly

TOWARDS PREVENTING SUICIDE

R W Parnell
D M Oxfd, M R C P
NUFFIELD RESEARCH PHYSICIAN

Ian Skottowe
M D Glasg, M R C P, D P M
PSYCHIATRIST

WARNEFORD AND PARK HOSPITALS, OXFORD

Deaths by suicide in England and Wales have been increasing, especially in the past few years In 1954 there were, according to the Registrar General (1954), 5043 suicides compared with 3447 in 1944—an increase of 1596 (46%) In recent years, moreover, their number has exceeded that of fatal road accidents, yet they attract much less public attention, and their prevention is seldom publicly discussed

Suicide is commonly committed in a mood of depression Since this state of mind is usually amenable to treatment, it should be possible, by earlier and more effective recognition of it, to reduce the number of suicides The fact that suicides have increased with more widespread use of physical treatments has led some workers—e g, Frost (1956)—to question whether physical treatments are being adequately supported by other measures, or even, it seems, to question the value of electroconvulsion therapy, although Maclay (1953) has called attention to evidence (Huston and Locher 1948, Fetterman et al 1951, Slater 1951) of the preventive value of electro convulsions

Four Questions

The general attitude to suicide varies in different cultures, but, if it is accepted that suicide should be prevented, all possible steps, both medical and social, towards this end need examining The prospect for more effective prevention depends on the answers to the following questions

(1) Is there a sufficiently large proportion of actual suicides who have not received full medical and social help ?

(2) If so, what warning signs can be discerned ?

(3) Is there evidence that admission to mental hospital is preventive not only in the sense of immediate prevention by constant observation but also in the sense of reducing the prospect of future attempts ?

(4) What evidence is there of the frequency of particular diagnoses among those attempting or committing suicide, and that those showing warning signs could be persuaded to enter mental hospitals, if most of them were not so manifestly ill as to warrant the making of an order under the Lunacy and Mental Treatment Acts (1890–1930) ?

EXTENT OF MEDICAL HELP

That a large proportion of suicides have not received help is shown by a series of 100 consecutive suicides from inquest registers of 1949–56 together with the information kindly provided by two coroners who noted whether the suicide had been under medical care

Not under medical care (including 4 where it was refused)	53
Under medical care	
Under general practitioner	17
Under general practitioner and consultant psychiatrist	10
History of having been in a mental hospital during the past year or so *	13
Not known	7
	100

* Among the remainder there were 7 who had been admitted to a mental hospital more than a year before committing suicide

The majority had not received medical care and, so far as is known, only 13% had been lodged at some time during the year or so before their deaths in a mental hospital, and 27% had recently attended their medical practitioner but had not been admitted to hospital This analysis suggests that there is plenty of scope for prevention, provided that warning signs are recognised

WARNING SIGNS

A previous attempt at suicide had been made in 11 cases Sainsbury (1955) reported 9% Statements such as that death came as a surprise were recorded in only 6 cases altogether, and even here not always as a surprise to all the suicide's associates, although it was to either family, doctor, or employer It seems that warning signs were present in the majority Their recognition comes next and supports this first impression of their frequency One coroner had recorded statements to the effect that the deceased had been noticeably depressed or worried in 42 of 74 (57%) of his cases, and in 8 others comments concerning insomnia, violent temper, or nervous breakdown suggested the relevance of psychiatry The next largest group, 21 of 74 (28%), was associated with recent surgical operations (8 cases), recent childbirth (2 cases), long lasting pain or severe illness (9 cases), and fear of this or fear of mental illness or mental hospital (2 cases) In the third group social causes related to marriage or remarriage (5 cases) and to fear of or impending legal action (4 cases)

In summary, so far it may be said that a change of mood with the appearance of depression, worry, or hopelessness appears as much the commonest warning sign

PREVENTIVE EFFECT OF ADMISSION

The number of suicides during residence in a mental hospital is small, for example, in 1954 there were only 51 suicides in mental hospitals out of the total of 5043 among the general population The suicide rate in mental hospitals was slightly higher than in the general population, but the mental-hospital population is much more highly disposed, as can be inferred from the frequency of attempted suicide among patients before admission to mental hospitals In our psychiatric and somatometric survey of newly admitted patients at four mental hospitals in the Oxford region we found that an attempt at suicide was a prominent reason for admission in 9% of 445 men and 10% of 521 women Furthermore, there was a history of a previous attempt in another 3% of men and 6% of women In so far as these proportions are representative, the figures enable an estimate to be made of the number of attempted suicides leading to admission to mental hospitals throughout the country This may be compared with the actual number of suicides

	Men	*Women*
Admission to mental hospitals in England and Wales (1954)	29,751	41 918
Estimated proportion attempting suicide	9 %	10%
Estimated number attempting suicide	2678	419
Actual number of suicides	3178	1865

It is evident that a much greater proportion of men commit suicide than of women On the other hand more than twice as many women attempt suicide unsuccessfully and gain admission to hospital as kill themselves These figures, of course, exclude many suicidal attempts not leading to admission to mental hospitals and cases of suicide where an open verdict is returned for lack of evidence They do, however, confirm earlier reports—e g, Stengel (1952)

In view of these three findings—the small number of suicides in mental hospitals, the very large number of unsuccessful suicide attempts arising from illnesses that are subsequently treated successfully in mental hospitals, and the small proportion (13%), among actual suicides, of persons previously treated in a mental hospital—it seems safe to conclude that admission does exercise the important preventive effect expected of it

PATIENTS COOPERATION

The prospect for further prevention would be dim indeed if potential suicides were all of temperament so independent that all refused outside help There are three main forms of evidence—personal, medical, and social—with which to answer this question

Personality Evidence from Physique

As mentioned above, somatometric data are available about patients attempting suicide There is already evidence that men of lean and muscular build are more disposed to suicide These findings we hope to report in greater detail when samples become large enough to permit further analysis by age It already seems clear however, that much overlap exists between the distribution of physical types found among healthy men men who only contemplate suicide, men who attempt it, and those who succeed, further the correlations between physique and temperament are unlikely to be so high as to exclude all hope of persuading potential suicides to enter hospital when the need arises

Stengel (1952) suggested that the two groups of people attempting and committing suicide formed two different populations These views derived partly from the assumption that suicidal intent was greater when single minded than when characterised as it is in so many unsuccessful attempts by a special appeal to individuals or to society for attention But Stengel also recognised the strong tendency for the two groups to overlap

Clinical Evidence

This has been collected from clinical examination by one of us (I S) and from an analysis of notes of patients who have attempted suicide to show the frequency of depression and other diagnoses (see table I) As is well known patients with affective disorders, such as anxiety and depression, are more likely to cooperate than those with thought disorder or psychopathic behaviour.

TABLE I—FREQUENCY OF DEPRESSION AND OTHER DIAGNOSES AMONG PATIENTS ATTEMPTING SUICIDE

—	Number	Dominant mood change		Disorder of thinking—e g schizophrenia	Other disorders (psychopathy hysteria &c)
		Depression	Anxiety		
Men					
Suicide attempt (reason for admission)	39	28	1	3	7
Previous attempt (not recent)	12	9	0	2	1
Total	51	37	1	5	8
Women					
Suicide attempt (reason for admission)	47	37	4	1	
Previous attempt (not recent)	33	22	1	3	7
Total	80	59		4	12

Depression was diagnosed in 72 5% of men and 73 8% of women attempting suicide It will be remembered that 57% of the coroners series were stated to have been noticeably depressed or worried Although psychiatric diagnoses and the statements of witnesses in court are not equivalent it seems that those who attempt suicide and those who succeed at least share the description of being depressed Dominant changes of mood, especially if anxiety states are included with depression account for or are at least associated with, the great majority of suicidal attempts Abnormal, antisocial, and other psychopathic behaviour, without prominent change of mood or thought, was seen in 12 (14%) of 86 patients who had recently attempted suicide Batchelor (1954) has suggested that such a diagnosis is appropriate in up to 25% of patients admitted to the observation wards of a general hospital after attempted suicide Such cases, because of their frequent impulsiveness may be harder to prevent but even in general hospital experience they are not very common From the preventive point of view the most significant fact in the present findings is the small number of patients showing disorders of thinking, the change so often regarded by the general public as a sine qua non for admission to a mental hospital.

TABLE II—FIRST ATTENDANCES FOR CONSULTANT PSYCHIATRIC ADVICE FIRST ADMISSIONS TO HOSPITAL AND ATTEMPTED AND ACTUAL SUICIDES AMONG OXFORD STUDENTS IN 1953–56

First admissions to Warneford Hospital	10	20	12	19
Attempted suicide	[illegible]	[illegible]	0	2
Suicide	4	2	0	1*

* Oct 15 1956

Social Evidence

Parnell (1951) drew attention to the number of suicides among Oxford University students By the end of 1953 there had been 15 suicides in seven years, an average of more than 2 a year In the three years from July 1953, to July 1956, there were only 2 suicides—in men aged more than 33 working largely on their own for postgraduate degrees Though no claim could be fully justified that comparative freedom from suicide among undergraduates in the past three years is due to social action it is appropriate to recall that, from 1951 onwards successive vice chancellors took steps to awaken wider interest in this problem The results are certainly not discouraging It is reasonable to suppose that greater willingness by tutors and others in frequent contact with students to recognise the implications of an alteration in mood or behaviour and to seek early advice from a college doctor may be partly responsible for whatever improvement has taken place It must be admitted however that the continuance of suicides of students elsewhere raises some doubts The incidence of mental ill health in general among students remains little changed and is summarised for the past four years in table II Because undergraduates are free to seek advice wherever they choose, and may do so in London or elsewhere during the vacation as well as at other hospitals in Oxford, the figures should be regarded as minimal.

With an average of 5951 male students in residence in 1952–56 the minimal annual first-admission rate to mental hospital is roughly 25 per 10,000 For the general population of similar age the figure was 11 per 10 000 in 1951 but this included a small proportion of readmissions For students, therefore, not only is the admission rate high but also the total rate may be higher, and the figures provided for comparison with other young men underestimate the difference

The following extracts from statements of witnesses at inquests emphasise both warning signs and social attitudes

Change of mood

"He was very depressed, which was something quite new"

"He was a cheerful man until the last fortnight but became very depressed He had had a previous breakdown"

"He had been unwell for years, but for a few months before his death had been very depressed"

Possible delay in obtaining advice

"He had been in abnormally good spirits six months ago but since then depressed and unable to concentrate On the night before he died we were discussing him and agreed it was desirable he should see his family doctor or a psychologist"

Moral attitude of witnesses

"He told me about his previous attempt at suicide, and I said he must snap out of that frame of mind, the best he could do was to stick it"

"He said he had been very depressed and that it had taken the form of a very strong temptation to commit suicide He had been quite *normal* in conversation"

The last quotation illustrates the emphasis placed on so called normal or logical thought as a reason for not seeking medical advice Our evidence points to the primary importance of a change of mood, illnesses in which disordered thinking is prominent are comparatively seldom associated with suicide Even here depression is likely to form part of the picture, as in the report "He thought he had cancer (although the doctor told him he had not) and he had been ever so depressed" If the occasional patient is illogical, the logical one may be even more difficult to manage

"Dr X said that the patient was a logical man whom he would have been unwilling to certify as insane in order to obtain shock treatment" This particular patient had been adamant in refusing hospital care, but his wife thought she could have persuaded him Persuasion, therefore, by all concerned is indicated

Lastly, a common report "He had never threatened to commit suicide" Direct questioning will often reveal otherwise concealed intentions Sometimes direct questioning is avoided for fear of putting suicidal thoughts into a person's mind This is a mistake Once a patient has admitted that he feels depressed, frightened, or hopeless, leading questions about the depth of his depression can and should be asked There is no evidence that such questions, put in a proper way, have any aggravating effect on the depression—rather the reverse, for confession often brings relief—or ever drive to suicide a patient who would not otherwise contemplate it A rough guide is needed to the depth of depression Does it cause the patient to weep without knowing why, or to feel that he wishes he could cry although unable to? Does he feel that life is not worth living? Has he thought of doing anything about it? If so, what? This is no time for hesitation in using all means of persuasion To prevent suicide people should forget about logic as a sign of health and remember that many more lives are saved by getting depressed patients to hospital than by applying tourniquets for hæmorrhage or artificial respiration for drowning Skottowe (1955) reported that nearly a third of his patients with depression had been ill for more than a year at the time of their admission to hospital The frequency of depression in general practice has been well described by Watts (1956), who emphasises how often it is overlooked

Choice of Method

Brooke (1956) has drawn attention to the increasing use of coal-gas poisoning and barbiturates during recent years In the coroners' series of suicides here cited, 48% died from coal-gas, 9% from barbiturates, 6% from aspirin There was evidence that barbiturates and aspirin were chosen more often by city dwellers, whereas more violent methods of shooting, hanging, and drowning were commoner in the rural area concerned Obviously it is desirable to stop the public from obtaining lethal doses of dangerous medicines too easily, but the number of 391 suicides by barbiturates in England and Wales in 1954 is only a small proportion of the total Since the choice of method is partly dictated by the means available, it is clear that effective prevention is more likely to depend on correct management of depressed people during the severe phase of their depression

Conclusions

In a consecutive series of 100 suicides a majority (53%) had not received medical advice Only 13 had *been in a mental hospital in the year preceding death*

Warning signs were present in the majority A change of mood, with depression prominent, was commonest Previous attempts had been made by 11 suicides

Evidence is presented that admission to a mental hospital has the preventive effect expected of it

(1) The number of suicides in hospital is small

(2) Large numbers of patients who have made unsuccessful attempts at suicide are subsequently treated successfully in mental hospitals

(3) Only 20% of actual suicides had ever been *treated in a* mental hospital

Analysis of hospital notes of patients attemptin suicide shows the paramount importance of mood change and depression Disorders of thinking are comparativel uncommon

The high incidence of mental ill health among Unive sity students, judged by mental-hospital admissio rates, remains unchanged, but the number of suicides Oxford University has dropped since widespread publ and private discussions brought better *recognition* this problem

Newspaper reports indicate the need for a change the attitude of the public The dangers inherent depression must be grasped more realistically, as well the favourable outlook with treatment That a patie does not threaten suicide, or again that he spea logically, is no excuse for inaction When depression recognised, leading questions about suicidal thoughts a necessary to gauge the risk

Choice of method for committing suicide is influence by the means available Control of drugs is importan but less important than control of patients' depression

We wish to thank Mr T E Gardiner and Dr L J Timm coroners for Oxford city and West Oxon respectively, wh kindly sent us extracts from their records, Dr R W Armstrong, Dr W Ogden, Dr S Last, Dr R G McInne and the other psychiatrists who kindly permitted us t measure and interview patients under their care, and D W S Maclay for the figure for suicides in mental hospital This work was undertaken during tenure by one of u (R W P) *of a grant from the Nuffield Foundation*

Before Our Time

OLD MOORE AND HIS ALMANACK

A Tercentenary

In his FitzPatrick lectures of 1913 Charles Mercier gave a remarkably lucid account of the science and art of medical astrology. He traced its written history from about 4000 B.C. and emphasised its paramount importance to medical men down to at least the period of the Renaissance. He then referred to its decline and wrote: "Astrology is now utterly extinct. It has been dead so long that it no longer stinks; perhaps because it is embalmed in the writings of so many men that were eminent in their day." If astrology was dead in 1913 it has certainly come to life again, witness the innumerable columns in the popular press devoted to "planning with the planets" or "what the stars foretell" and the enormous trade in "horoscopes". Quite recently, too, a London surgeon revealed that patients frequently ask him to operate on a day which they regard as propitious; and he very properly grasps this opportunity of sharing his responsibility with the stars. If any further evidence is required of the vitality of the ancient art of astrology it is provided by the number of Almanacks and Prognostications which continue to pour from the press. The most remarkable of these from the point of age is *Foulsham's Original Old Moore's Almanack*, which is the lineal descendant of an almanac compiled by Francis Moore in 1699 and which has apparently been issued without a break since 1701. The certified net sale of *Old Moore* at the present time exceeds one and a half million copies annually.

* * *

Francis Moore was born at Bridgnorth, Shropshire, on Jan. 29, 1657. He is said to have acted for some time as assistant to the notorious astrologer John Partridge (1644–1715). Having obtained a licence to practise physic—presumably one of the Bishop's Licences which constituted one of the few legal qualifications open to general practitioners at that time—he established himself in 1698 at the sign of "Dr Lilly's Head" in Crown Court, near Cupid's Bridge, Lambeth, in the capacity of physician, astrologer, and schoolmaster. In 1702 he was living near the Old Barge House in the parish of Christchurch, Southwark, where he probably died between July, 1714, and July, 1715.

In 1699 appeared an almanac entitled *Kalendarium Ecclesiasticum*, by Francis Moore, Licensed Physician and Student in Astrology. This duodecimo of 48 pages contains a table of the Kings of England, the Law Terms, tide tables, astronomical data, and a list of fasts and feasts, in addition of course to the calendar. The prophecies are confined to the weather. The only sections of direct medical interest are the list of the Signs of the Zodiac with the parts of the body which they are said to influence, and short notes placed at the head of the calendar for each month. That for January reads:

> "Let not blood this month unless necessity require it. Be careful of taking cold, for thereby Rheum and Flegm is much increased. Fast not long in the Morning, for it is hurtful. Use Meats moderately hot. Warm Cloaths, warm Diet, a good Fire and a Glass of Sack with a Toast is very seasonable, if you can get it."

The heading for March says:

> "In this month advise with the Astrological Physician, for now Purging and Blooding is good. Blood and Humours increase, therefore now be sure use Meats of good Digestion, forbear salt Meats as much as possible, now good Drink is necessary; but above all, a good Breakfast, if you can get it, will do no harm."

The phrase "if you can get it" is often repeated, and it suggests that Moore, like most of his kind, rarely looked on the bright side of things. In his later almanacs, which give much greater space to prophecies, he illustrates one of the most constant characteristics of the early prognosticators—their almost entirely unrelieved gloom. Perhaps it was that plague, pestilence, famine, and sudden death were fairly safe things to foretell.

Moore's literary style, like that of many of his medical contemporaries, is by no means lacking in grace and vigour. His note for the month of May begins quite poetically:

> "Now both Garden and Field afford Physick as well as Diet. Rise early, and walk abroad by the running Streams. Sage and sweet Butter is a cheap and wholesome Breakfast. Clarified Whey, with Sage, is also good, and so is Scurvy-grass Ale and Wormwood-Beer. Forget not to eat and drink betimes, you that have it."

With the last page of this little book we come to what was probably the main reason for its publication—an advertisement for Moore's wonderful pills:

> ADVERTISEMENT
>
> From Crown-Court, near Cupid's Bridge, in Lambeth Parish, in Surry, Aug. 15, 1698.
>
> Where is sold, by the Author, his Famous, Familiar, Family, Cathartick and Diuretick Purging Pill, very excellent for the Scurvy, Dropsie, French Pox, and most other Distempers incident to the Body of Mankind. They work so gently, that you may take them at any time of the year; they hinder no Business. A Note of Direction will be given with each Box, which contains 40 Pills, for 2*s.* and the Half box, containing 20 Pills, for 1*s.*

* * *

In July 1700 Moore completed a new almanac: *Vox Stellarum; being an Almanack for the Year of Human Redemption 1701*. This was dedicated to Sir Edward Acton, recorder and M.P. for Bridgnorth, Moore's native town. The general make up is similar to that of its predecessor, but *Vox Stellarum* contains much more of medical interest. The twelve Signs and their dominion over man's body are now set out in verse, and each page of the calendar has a column of medical notes. Thus for January—

> "Full Moon the 13th day at 1 afternoon will undoubtedly be made sensible of its Effects. They both cast an anxious Square to Venus, which threatens Females in general with stubborn Diseases, especially such as do proceed from Cold, which may turn to violent Fevers even at this time of the Year, and send some to the Shades, whilst others are swallow'd up in the Grave of despair; and an eminent Lady afflicted with much Sorrow, if not Death."

The last page again contains an advertisement:

> "By the Author hereof (only) is sold his famous familiar Family Cathartick and Diuretick purging Pills.
>
> The Author also thro' the Blessing of God, cures all sorts of Agues at once, whether Quotidian, Tertian or Quartan, tho' of long standing, and left off by others, as many now living can testifie, who have by God's Blessing, been cured by him at last. This Distemper often comes by supernatural means, which is the reason it will not yield to natural means, nor be subject to the will of every Pretender; nor indeed many other Distempers besides. The Author also has an excellent Method and Medicine for the Epilepsia or Falling Sickness, and Convulsions in Children. He gives his Judgment *gratis* to all that come to him, and allows his Medicines at reasonable Rates. *Vivat Rex.*"

* * *

Francis Moore was not of course the first maker of almanacs. Almanacs, Kalendars, and Prognostications were among the earliest productions of the printing press and they have been issued in enormous numbers at all periods. The first Englishman to produce a printed Almanack and Prognostication was the famous Andrew Boorde in 1545. Moore himself had a host of rivals. The copy of the 1701 issue of his *Vox Stellarum* in the British Museum is bound up with 26 other almanacs for the same year. Among the more famous of Moore's immediate predecessors and contemporaries were his teacher John Partridge, William Lilly, William Andrews, John Gadbury, William Salmon, and George Parker. Almost all the early printed almanacs were the work of medical men. Some of the compilers were regular doctors of physic, but the majority were, like Moore, "licensed physicians," or "students in astrology and physic"—the general practitioners of the day These little books represent a prime source—as yet virtually untapped—for the study of the connection between astrology and medicine, for the history of certain aspects of medical practice and its regulation in this country, for the biography of many practitioners of great repute in their day, and for the history of medical advertising Many of the early almanacs are exceedingly rare, only one or two copies, and these imperfect, having survived Very few of the compilations that have appeared over a number of years exist in complete sets In continuity, *Old Moore* is unrivalled, and its successive issues would provide a fascinating picture of the changes in popular medical beliefs and fashions over a period of more than two and a half centuries

It may be noted that the present day Old Moore does not offer any medical advice at first hand His Almanack contains a great many advertisements for hair restorers, depilatories, rupture cures, slimming tablets, and oriental herbs of great potency It also includes portraits of the Misses Marilyn Monroe and Dawn Addams, and a Pools Forecast for 1957 One is glad to see that the anniversaries recorded for January include the birthday of a former secretary of the British Medical Association, but oddly enough the nativity of the genuine, original Old Moore himself, on Jan 29, 1657, is not mentioned

Public Health

B C G Vaccination

IN his annual report for *1955*, *Dr W A Horne*, medical officer of health for Glasgow, refers to further extension of B C G vaccination in the city The total number of vaccinations performed again increased, and immunisation was extended to include further groups, notably Glasgow Police Force During a period of seven weeks 118 schools were visited and some 12,000 children were tested, of whom over 8000 received vaccine Two features of the campaign were notable—the striking increase (10%) in public response and the rise of almost 7% in the number of negative reactors, compared with 1954

Almost 1300 members of the police force accepted the offer of B C G vaccination, and the results of Mantoux testing showed an unexpectedly high number of negative reactors, the over all average being 13 4% It was also surprising to find that negative reactors were distributed among all the ages tested, which ranged from 20 to 57 As a result of these findings, Mantoux testing, followed by vaccination if indicated, has been made a requirement for entry to the Glasgow Police Force

The London County Council has had made a three-minute coloured film entitled *B C G Vaccination*, to be shown at local cinemas throughout the county during 1957 It encourages parents to allow their children to be tuberculin-tested, and vaccinated if the test is negative

Births and Deaths in 1956

Provisional figures for England and Wales in *1956* have been issued by the Registrar-General [1]

Live Births —The birth rate was 15 7 per 1000 population—the highest rate since 1950

Infant Mortality —The infant mortality rate—23 8 per 1000 related live births—was the lowest annual rate ever recorded in this country The rate was 24 9 in 1955, 25 4 in 1954, 26 8 in 1953, and 52 8 in 1938

Deaths —The death rate was 11 7 per 1000 population The rates for 1955 and 1954 were 11 7 and 11 3

Stillbirths —The stillbirth rate was 23 0 per 1000 total live and still births In 1955 the rate was 23 2 and in 1954 23 5

In England Now

A Running Commentary by Peripatetic Correspondents

WE have geologists the way some folks, as Thurber would say, have mice Into a biological department they introduce large piles of crazy paving (the floor has had to be reinforced) and enormous wooden boxes Not content with this, they telegraph us from remote areas "Have found dinosaur stop send *packing case* eight by six by four stop" We found one, by a fluke, but on that day the van was wanted for the agronomists' annual wayzgooze, and we had to despatch the thing to Waterloo on a handcart pushed by two junior technicians All went well as far as Fleet Street There a wheel came off Fresh from an initiative test, the two juniors ditched the cart, removed the lid of the case, laid it on the inverted body, and finished the journey inside, like a panto horse, navigating blind and led by a policeman

Only a few days later, another of the geological boxes produced a surprise Its owner came in to see me with a vague expression on his studious face and a dirty block of apricot table jelly in his hand, divided up into squares as such things are "I want you to look at this" he said "Do you think the same about it as I do?" It was wrapped in oiled brown paper I smelt it, tasted it, put a piece in water, agreed with him that it was a half pound chunk of blasting gelatin, and offered to take it up on the roof and destroy it When he refused this unselfish offer (I suppose he thought it would go off and damage some of his lumps of rock) I told him to take it down the road and hand it in at the police-station

Half an hour later he was back "I gave it to the duty sergeant" he said "the chap agreed that it wasn't a table jelly He said he was going to put it down the toilet and pull the string, and he went and did"

So if a member of the Force becomes the first artificial satellite vehicle, *I expect they'll blame that lot on Archbishop Makarios too*

* * *

An enforced rest in a small ward of one of our great hospitals has lately given me an opportunity denied to surgeons and their anæsthetists of observing preoperative treatment

The operations on two young men aged about 11 were set for 4 30 P M When lunch passed them by they seemed sad One confided to a passing porter that he would be glad when it was half past four

"Why, are you going home then?"
"No, that's when I have my operation"
"Oh, you'll know nothing about that"
"I know, but it's the injection I don't like I say, tell the staff nurse we're hungry"

This, of course, had no effect But one of them soon found the remedy in the jar of sugar in his locker and consumed a fair quantity This gave him the energy for preoperative physical exercise such as lifting the bed table up and down with his feet and playing ball with his neighbour All this makes me, a mere physician, wonder how much anæsthetists really know about the preoperative stomach contents and blood-sugars of their patients

* * *

Last week, in Boston, I gave four set talks, and also three little speeches on ward rounds I am hoarse without *emotion But this is a great country* for the medical *visitor, for there is something he can be doing* all the time in the way of meetings, panels, discussions, seminars, or even just drinking good coffee They also manage to keep their students keen and interested throughout the course instead of falling into exam-ridden apathy in the final year Most of this is, I think, due to their large staff *in proportion to patients and students*—but it's not all logistics, there is also an attitude of mind (which I admire) which makes for uninhibited discussion by folk of all levels of seniority (and intellect) I'm not entirely enchanted, however I keep in mind that I've only seen the best places, and also that the large staff and the *attitude that it's all great fun may* sometimes bear hardly on the patient, especially if he is coloured and perhaps a bit simple I may be wrong about this—it may be that the Americans are getting the medicine they deserve, they certainly pay enough for it I'm amazed by the popular interest in health, and I guess that office doctors here have to read advance copies of *Time* and the *Reader's Digest*

Luke is a dales farmer A good one, but with a reputation for meanness and a capacity for getting anything that is going from the Government or Anybody Else Recently he became a grandfather for the first time and was more than delighted with the arrival of twin grandsons When I saw him on market day last week, I ventured to congratulate him on his new status and especially on the twins "Aye," he said, "ain't it a grand thing Straight into t' subsidy first time"

* * *

This week John came out in spots Too much porridge, perhaps, his mother thought "I am quite worn out with porridge," said John wearily

* * *

Lord Osis disliked the Health Scheme because he could no longer annoy his doctor by owing him money He had his blazonry inscribed upon his N H S card and dispensed specimens of his urine in Veuve Cliquot bottles of a particularly brilliant year He was a small sunburnt man with tufted hair, like an indignant coconut, and, as his message was late (as usual) and urgent (as always), I called on my way to the night train by which my chief was returning, and I, his locum Ananias, departing

Lady Osis, large, rufous, and wrinkled like a Californian sequoia tree—which she further resembled by adding a ring for every year of her age, thus making her look as though she had been pebble-dashed with diamonds—broke trail along the landing to His Lordship's bedroom through the Osis fan-club of retainers, valets, grooms, secretaries, and dogs, which she trampled underfoot or ground unconcernedly against the wall

"He's swelled up like a poisoned pup!" she bellowed, cheerfully unveiling her groaning and tympanitic spouse and suggesting almost unlikely cause for his distension "Now if he was a cow," she added, presumably following the train of thought inspired by his dismal noises, "do you know what I should do?"

I didn't know, and still wish I still didn't know, but I adopted my best manger-side manner and examined the patient's abdomen by proceeding over it upon a Great Circle course It was, I concluded, a case for masterly inactivity plus a good old-fashioned turpentine stupe

"Turpentine?" shouted Lady Osis at my request, "Good God!" Are you going to paint pictures on it?" and made suggestions about selling advertising space, before issuing commands at the bedroom door Long minutes passed, during which Lord O retired under his bedclothes like Achilles sulking in his tent, his wife rent strips off a moth-infested horse-blanket, and I beat frenziedly with my dressing-case upon the hordes of dogs which were now surging about the room A timid voice then informed us that there was no *turpentine*, and Her Ladyship erupted on to the crowded landing with the impact of a violently propelled cue-ball upon a snooker "pyramid" Bodies shot off in all directions into every orifice, and the noises of ill-usage of drawers and cupboards reverberated like the cannonading at Austerlitz

When the barrage lifted I received a grimy cobwebby bottle with no label and an impacted cork This, with several spiders, was removed by Lady Osis with a corkscrew she happened to be wearing I sniffed the bottle, the smell was aromatic, but I couldn't identify it Her Ladyship, however, brandishing her strips of horse-blanket in a blizzard of moths, cried, "Get to it, boy! I know turpentine when I see it!" and the stupe was lashed into place

My nose twitched thoughtfully as I drove to the station but not until I entered the newly decorated waiting-room was my olfactory problem solved I told my chief through my carriage window, "You'll find all the case records in the car, and when you visit old Lord Osis, take along a blow lamp I've made his turpentine stupe with coach varnish"

Letters to the Editor

TREATMENT OF SORE THROAT

SIR,—The paper by Captain Brumfitt and Captain Slater (Jan 5) and the letter last week by Dr Wheatley raise important principles on the use of antibiotics in general and in sore throats in particular

My own interpretation of the two divergent points of view expressed is as follows Brumfitt and Slater have shown that the place of antibiotics in the treatment of acute sore throat is still doubtful, both as regards which cases should be treated with these powerful drugs and as to whether the results are really very much different from those treated with non specific measures Wheatley on the other hand advocates that *all* cases of sore throat should be treated with *oral* penicillin in order to prevent complications related to strepto coccal infections He also states that it is the general practitioners whose views on the matter should be listened to (But what, if not general practitioners, are the National Service medical officers?)

I feel that certain relevant points should be appreciated

Ætiology—What is the cause of the hundred odd cases of acute sore throat that the average family doctor sees each year? The usual finding from throat swabs is that only about half will grow any organisms that are usually recognised as pathogenic In my own practice in the past 400 cases of sore throat in adults hæmolytic streptococci were grown from only 45% What is the cause of the other 55% of cases? If these are not caused by specific organisms, then what is the rationale of using specific antibiotics?

Course—Acute sore throat tends to clear up spontaneously and uneventfully after four or five days If oral penicillin is to be advocated, then we should be shown that beyond doubt this shortens the illness

Complications—It is because of complications that the wholesale use of antibiotics is usually advocated It is stated that their universal use has brought about the dramatic decline in the numbers of new cases of rheumatic fever and acute nephritis But very probably the hæmolytic strepto coccus was beginning to lose its virulence even before these specific drugs were being widely used In my own practice I find that I am using penicillin in only 20–25% of cases of acute sore throat, the proportions being equal in streptococcal and non streptococcal cases In spite of these low proportions, in the past ten years I have had no cases of rheumatic fever and only 4 cases of acute nephritis, 2 of these were treated with parenteral penicillin, and the other 2 were so mild that they did not feel it necessary to consult me Acute otitis media, mentioned in Dr Wheatley's letter, is also a much milder disease, and in spite of using antibiotics in only 20% of cases I have had no acute mastoids or chronic running ears or permanent deafness in these ten years

The advocation of the wholesale use of oral penicillin causes me considerable disquiet on two scores First, its very ease of administration leads to possible abuse Secondly, its absorption is doubtful in some cases, and we often find that our instructions are not followed by some patients who omit to take the preparation and still recover uneventfully My own routine is to use only the intramuscular route and to give all the injections myself—the extra trouble to doctor and patient acts as a brake on facile use and abuse

The time has surely come for us to reflect and review our habits in the use of antibiotics and to take into account the natural changes that have occurred in the common diseases for which they are so often given

Beckenham, Kent JOHN FRY

SIR,—To me there seem to be three important points in Dr Wheatley's letter

(1) The treatment of sore throat is *primarily the task of the general practitioner* This is indisputable, but medicine depends for its advancement, *not* merely on intelligent observation but on painstaking and controlled investigation which the average practitioner, because he lacks either facilities, or—that more important commodity—time, is not in a position to undertake Brumfitt and Slater are to be

commended for their perspicacity and initiative in seizing the golden opportunity of studying scientifically this common malady

(2) *Penicillin lozenges*, not intramuscular penicillin, is the means of administration which the overworked practitioner must adopt But if blood borne penicillin cannot eradicate the streptococci lurking in the depths of the tonsillar crypts, what chance has the superficially acting penicillin lozenge ?

(3) Dr Wheatley attributes to antibiotic therapy the decreased incidence of local septic complications and toxic allergic sequelæ of sore throat Yet I have treated 73 sore throats—some of them quite severe—without antibiotics and I have not had a single case of septic involvement of the middle ear cleft, and has the reputedly high incidence of rheumatic fever and acute nephritis ever been conclusively proved to be higher than it is today ?

Dr Wheatley says nothing about the risk of inducing resistant strains of bacteria by indiscriminate use and inadequate dosage of the antibiotics Nor does he mention the risk of sensitising the patient He has, I think, been fortunate not to have met the nasty stomatitis which can develop during penicillin lozenge therapy

I wish that Brumfitt and Slater had not been so hesitant in interpreting the obvious lesson of their inquiry, which has exposed the uselessness of routine penicillin for sore throat and which should lead to a further saving of this big gun for big occasions

Royal Air Force,
Leconfield
A R SMITH

SIR,—Dr Wheatley suggests that information on the treatment of sore throat be sought from general practitioners May I draw his attention to a recent report on the treatment of acute sore throat in general practice? [1] If Flying-Officer A R Smith (Jan 19) reads this paper he may change his view that "nothing is to be gained by giving antibiotics or sulphonamides" in acute sore throat

St Mary Cray, Kent
E TUCKMAN

SIR,—In my opinion there is far too much tendency to prescribe sulphonamides, penicillin, or the broad-spectrum antibiotics for the ordinary follicular tonsillitis seen in general practice

Tonsillitis being a simple infection of the upper respiratory tract, it follows that simple measures will suffice I find that rest in bed for 3–4 days, combined with mist acid acetylsalicyl *N F* and an abundance of bland fluids, will in the vast majority of cases be all that is required It is important that a child should not return to school for at least another 4 days, and an adult for at least a week

Of course, where there is any underlying condition, such as congenital or acquired heart-disease, or a past history of rheumatic fever, it is imperative that either a sulphonamide or parenteral penicillin be given

Putney
BERNARD SWEETMAN

THE Rh BLOOD-GROUPS

SIR,—Dr Wiener's letter of Jan 12 is full of confusion which suggests that he does not understand the CDE notation

Dr Nicholas last week showed how misleading Wiener's two tables are as presented Had this been the only inconsistency it would not have been so bad, but there are other statements which may lead the unwary astray Thus, Wiener says that anti-C and anti-D are less rational names than anti rh′ and anti Rh_0, and gives the following example "corresponding to the gene symbol r'^w, Fisher and Race use the 'chromosome' symbol C^wdeF, which includes the letters d and F for antigens for which no testing sera exist " But *d* and *F* do not here stand for antigens but for genes, and should therefore have been in italics The example is, therefore, irrelevant to the argument One cannot maintain that a gene may not have a symbol simply because no testing sera are known Therefore, one can only conclude that, in his mind, Wiener has confused symbols for genes with those of their products

If Wiener really wants a logical nomenclature he should follow that given by Ford [1], the most logical yet formulated

Department of Zoology,
University of Liverpool
P M SHEPPARD

BLOOD-GROUPS AND DISEASE

SIR,—Dr Wiener's letter of Dec 22 seems to call for some comment, although his bias against any idea of an association between blood groups and disease (other than hæmolytic disease of the newborn) is well known Far from being a waste of space, the publication of data, however fragmentary, concerning the genotypes of groups of patients, compared with those of satisfactory controls is essential if progress is to be made in understanding the inherited basis of disease

Instead of denigrating new work, most of which has been much more carefully controlled than that of thirty years ago, *it would be more profitable for so eminent an* authority on immunology (he is, after all, one of the discoverers of the Rh blood-groups) to try to integrate the following *facts*, which suggest that there may be immunological processes operative in peptic ulceration

(1) That in six countries, the U S A included, many authors have demonstrated a marked association between blood group O and peptic ulcer This is the most striking of several apparent associations between blood groups and disease It can hardly be due to chance that, of the many disorders studied, all the positive results concern diseases of the gastro-intestinal tract, carcinoma of the stomach, pernicious anæmia, and duodenal and gastric ulcer

(2) That there is a strikingly higher proportion of non secretors of the ABO blood group antigens in duodenal ulcer patients compared with general population controls This association has also been shown to hold within families The data also suggest, though they do not yet prove, that the association is greatest in those sibships which do not segregate for blood group O

(3) That within sibships the association between blood group O and duodenal ulcer is not apparent though not disproved [2]

(4) That drugs such as corticotrophin, cortisone, aspirin, and phenylbutazone, all of which cause or exacerbate peptic ulceration in man, also have an effect on antigen antibody reactions and are frequently used in the treatment of hyper sensitivity states

(5) That many leguminous plants which form an important constituent of human diet contain ABO blood group agglutinins many of these will be neutralised in secretors but not in non secretors (see accompanying letter by Cain)

The initial cause of mucosal damage in patients with peptic ulcer is quite unknown, and it seems to us that there is a good prima facie case for investigating the possibility that immunological reactions play a part in the genesis of ulceration

---

[1] Ford E B A uniform notation for the human blood groups *Heredity* 1955 9 135

[2] References relating to paragraphs 1, 2, and 3 are Fraser Roberts, J A Aird, I Bentall, H H, Mehigan J A Wynn Edwards J *Brit med J* 1954 ii, 315 Clarke C A Wynn Edwards J W, McConnell R B Sheppard, P M *Ibid* 1956, ii, 725, Anonymous Haddock D R W, Howel Evans A W, *Ibid* p 723

[3] Mourant, A E Distribution of the Human Blood Groups Oxford, 1954

[4] Ford E B *In* The New Systematics (edited by J S Huxley) Oxford 1940

that (at least until extremely recently) it has been maintained by stabilising selection, which in turn implies that both secretors and non secretors have some definite selective values On the advantage of non secretors it is useless to speculate until we know something positive about the condition, but one possible selective advantage of secretor can be suggested

As Fisher [5] and others have shown, a selective advantage of as low as 0 5% can bring an allele to fixation in a population comparatively rapidly, and field studies [6-8] have shown that apparently very trivial characters, when properly investigated, may have startlingly high selection coefficients Moreover the different effects of alleles can be profoundly altered by selective accumulation of modifiers [9] Consequently, so well-marked a condition as secretor is exceedingly unlikely to be a mere by-product of some other important effect of the allele It is far more likely to be there for a definite purpose

The effect of secretor is to allow a considerable outpouring of antigens into the alimentary canal at its most anterior part This suggests immediately that something is being taken in, as part of the food, which it is advantageous on the whole to neutralise as quickly as possible This substance could be one that would damage the free cell surfaces of the epithelium actually lining the alimentary canal, especially those which are absorptive and therefore cannot be covered over with some impermeable protective substance

The discovery that large quantities of blood-group agglutinins which can be neutralised by secretors [10] occur in the seeds of leguminous plants widely used for food goes far to support this hypothesis, and further suggests that these antibodies have a definite, if mild, deleterious action on some parts of the absorptive epithelium of the alimentary canal Such an action, even if of little importance to civilised man, might of course be of considerable importance under the far more strenuous conditions under which man has lived for many thousands of years The considerably lowered incidence of duodenal ulcer in secretors, as compared with non-secretors of the ABO blood group antigens,[11] suggests very strongly the actual nature of this deleterious action

The hypothesis proposed, therefore, is that ABO agglutinins deleterious to the absorptive epithelium of the alimentary canal, which are taken in as part of the food, are wholly or partially neutralised by secretors This hypothesis has the advantage of being susceptible of experimental verification

A J CAIN

A RAPID BLOOD-SUGAR SCREENING METHOD

SIR,—With the increasing interest in glucose enzyme tests and their application in urine examination, I should like to draw attention to a rapid blood-sugar screening test which is also based on the use of glucose enzyme test strips The method has been developed in this hospital The difficulties encountered in trying to apply the enzyme test to quantitative estimations in urine are not met with to the same extent in blood, which is far less subject to variations in chemical composition and pH In 500 experiments performed by independent observers in parallel with blood sugar determinations by conventional biochemical methods, it was found that, within certain ranges, there is a definite and constant correlation between the blood glucose level and the intensity of the colour developed on the strip

The technique consists in placing a drop of blood from a finger or ear prick on the tip of a glucose enzyme strip, leaving it there for about fifteen seconds, and then washing the blood off under running water The plasma soaks quickly into the filter-paper and the red blood-cells are washed off, permitting the reading of the result without interference from the colour of the blood The colour developed is compared with an arbitrarily chosen three tone colour scale The whole procedure takes less than a minute and no reagents are necessary

The test can indicate the following ranges of blood-sugar very low, low, normal and slightly elevated, moderately elevated, and high It does not require any particular experience and can easily be performed by any doctor A full report is in preparation

Queen Mary's Hospital
Roehampton, London, S W 15

J KOHN

ANALGESIC DRUGS IN CHILDBIRTH

SIR,—I was very interested in the paper by Dr Roberts and her colleagues last week and congratulate them on their investigation of an important and very difficult problem The use of levallorphan to diminish the respiratory depression caused by the narcotic analgesics in childbirth is one of the most valuable potentialities of this antagonist That its use did not result in a significantly improved minute volume in the infants may have been due to the fact that the dose of levallorphan was inadequate I believe that a 1 100 ratio of levallorphan and pethidine [1] might have given more satisfactory results

Manchester

MARK SWERDLOW

UNMARRIED PARENTHOOD

SIR,—It must have struck other readers of Mr Greenland's sensible paper last week on the ecology of unmarried mothers that it contained only one reference to the fact that pregnancy can be prevented by suitable measures If in fact the "unmarried mother" differs from her sisters chiefly in being more fertile, if efficient contraception may "tend to reduce the number of illegitimate maternities among the higher-income groups," if unmarried mothers sometimes die of abortifacients and unmarried babies often die of neglect, the point is surely relevant

I think that the trouble is that social agencies find themselves engaged in two distinct attempts—the prevention of unwanted pregnancy, and the attempted prevention of sexual behaviour in young people Their merits apart, experience suggests that the first offers better chances of success than the second "Moral welfare" has perhaps a real part to play in preventing married men from seducing unmarried women, and intelligent health and social education might inculcate a better idea of responsible sexual behaviour all round Unfortunately the devotion of moral agencies to the prevention of coition has often eclipsed their anxiety over the tangible suffering unwise coition may cause Some have regarded pregnancy as a desirable disincentive —few seem able to agree that, if they cannot prevent the initial step, it would be humane *to limit its* consequences

Obviously the venue and personnel of unmarital relations are not promising for fully reliable contraception, and it may be that no contraception is "fully reliable" But I imagine a halving—if we got no more—only of the death rate from abortion would gratify the devout as much as it would gratify me Unfortunately, while it took Parliament about seven days, all told, to legislate against contraceptives in slot machines, it has not implemented the recommendations of the Royal Commission on Population in seven years

[1] Swerdlow, M *Anaesthesia* (in the press)

I certainly do not underrate either the value or the interest of the sociological approach to local differences It might be well worth sending anthropologists to study the patterns of life which produce high outputs of illegitimate babies A study of the economic causes which hinder marriage would also be interesting, and probably useful, especially in Peru But while proper and general contraceptive education is no more an answer to a social problem than B C G is an answer to tuberculosis, it seems an obvious first step without it, as Mr Greenland says, " children will continue to die needlessly, many of those who survive will be miserable, and the unmarried mother will suffer for our indulgences as well as her own "

Loughton, Essex **ALEX COMFORT**

SHORTAGE OF RADIOGRAPHERS

SIR,—As a radiographer, I would like to challenge several of the points raised by Dr G H Illingworth (Jan 5)

Firstly, he claims that only male radiographers are dissatisfied with their salaries This is not the case Both men and women feel strongly about the present low figures, and resent the Whitley Council's unrealistic attitude to our salary claim Girls are beginning to realise more and more that there are plenty of jobs open to them with better remuneration and less exacting duties even in hospitals, let alone outside the N H S Male radiographers are, of course, becoming extinct There is absolutely no incentive to take up the profession, and there are strong inducements for those already in it to leave In fact, they are leaving, in scores Radiography will indeed be " a job for a girl " and will suffer in consequence

Dr Illingworth suggests that superintendents can largely be dispensed with Yet the efficient administration of all but the smallest departments, with only 2 or 3 on the staff, would take far more time than the average radiologist would be *willing or able to devote to it* Administration would inevitably devolve on the most senior of the radiographers, and she would soon find herself a superintendent in all but name

In so far as educational standards are concerned, Dr Illingworth himself defines just the type most desirable for X ray work " An intelligent girl of 17 or 18 with an aptitude for the work " We are surely not aiming too high in asking for a General Certificate of Education with a bias towards science subjects, to ensure filling the prescription, as it were

As for the membership examination, which, incidentally, most students have no difficulty in passing in the two year period, it is necessary to maintain our standard of knowledge at a reasonably high level, otherwise the quality of work will gradually suffer There has been considerable exaggeration of the abstruse nature of the physics and apparatus construction taught Only the fundamental parts and principles are dealt with, and any complexity is due to the diverse units and functions of a modern set (Several hundred pounds worth of damage can be done to a tube through ignorance of its properties)

I would like to register a strong objection to the implication in Dr Illingworth's letter that the Society of Radiographers is deliberately making its membership examination too difficult, *in order to limit entries and thus strengthen its hand* Under the all powerful Whitley Council our own society seems to have very little to say, as the recent negotiations have proved

Finally, a word about the training of staff Surely the approved training school, with its facilities for all types of special work, organised groups of lecturers, and so on, is the most efficient way of training personnel Learning radiography started in a haphazard pick it up as-you-go along way, as with all new sciences, but a better system has been evolved over the years, and it would be retrogressive to return to learning in the department alone In any case, it is becoming increasingly difficult for radiographers in the busy short staffed departments of today to devote all the time they should to the practical training of their students sent down from the training-school

SYRINGE CARRIER

SIR,—We doubt that the syringe carrier referred to by Dr Lerman (Jan 12) solves the problems of the anæsthetist

In our view, the time consuming labour is largely spent in cleaning, sharpening, lubricating, and assembling, all of which have to be done in any case, while saving is represented only by the time taken to insert the syringe in the container Using the Nuffield type of aluminium container this would *not be substantially greater, and Dr Lerman is mistaken in* thinking that these are expensive—they cost merely a few pence and can be damaged only by direct violence

The multiple syringe carrier has three disadvantages Firstly, by any one arrangement it must contain a fixed set of syringes, which may or may not accord with the demands of varying circumstances Secondly, the contents are rendered potentially non sterile on first opening, and subsequent openings add to the opportunities for contamination of all remaining syringes by air, droplets, or hands Since the " life " of one boxful may be prolonged, this is no small risk Thirdly, a syringe could be accidentally replaced in the box without necessarily giving any indication (e g , by the presence of a broken seal) that it had been used

We would expect cultures included in the box to be sterile after treatment by hot air or steam, but are more concerned at the results which might be obtained by placing a small plate of medium inside the box and examining it when the last syringe has been used

ALLOXAN AND CARCINOMA OF THE LIVER

SIR,—In their stimulating preliminary communication (Jan 12) Professor Gillman and his colleagues report that alloxan, given intravenously, seems to retard tumour *growth without causing diabetes* If this finding is confirmed, it will be of great theoretical interest, for there may be a fundamental link between it and the important discovery made long ago by Warburg[1,2] that in cancer cells respiration is decreased and glycolysis increased

Glycolysis proceeds at a lower oxidation reduction potential (Eh) than aerobic carbohydrate metabolism (respiration) It would seem, therefore, that if a substance which raised the Eh of the tissues were introduced intravenously it might block the main pathway, glycolysis, from which cancer cells derive their free energy, and so cause retardation of growth or even necrosis Alloxan has the potential properties of just such a substance

Both ascorbic acid and glutathione, when injected intravenously, lower the Eh of the tissues[3,4] *This was* first demonstrated by measuring changes in the decolorisation-times of oxidation-reduction dyes injected into the skin, and was confirmed by measuring directly the fall in the Eh of the tissues with an inserted electrode In *1954 I suggested that the term " reductosis "* might be introduced to describe this condition

" A disturbance resulting in a *tendency* towards a decrease in pH is called an acidosis, and one *tending* to an increase in pH, an alkalosis It is possible that analogous tendencies towards changes in the Eh of the tissues may occur as the result of disease and the administration of drugs , *tendencies* towards increase or decrease in the Eh of the tissues might be labelled ' oxidosis ' and ' reductosis ' respectively, corresponding to a decrease or increase of available electrons "

Although ascorbic acid and glutathione undoubtedly, and cortisone and corticotrophin probably, cause a reductosis, no substance has yet been shown to cause an oxidosis But alloxan and dehydroascorbic acid, which are found in Nature, might be expected to do so in

massive intravenous doses If in fact they do, they might also be expected to retard tumour growth, by direct action on cancer cells rather than through the intermediary of the endocrine system

There are three interesting questions

1 Does alloxan, in the doses given by Professor Gillman, cause a measurable oxidosis, and if so for how long ?

2 Does dehydroascorbic acid given in similar doses also retard tumour growth, and does it cause an oxidosis ?

3 If alloxan acts in the way I have suggested, then by analogy with the reductosis caused by the intravenous injection of ascorbic acid and glutathione one would expect the effect to last for only about an hour Is the retardation of tumour growth enhanced by repeated administration ?

G E LOXTON

HEAD INJURIES

SIR,—Mr Lowden (Jan 12) asks for guidance in the selection of cases requiring neurosurgical management May I suggest that he solicit advice from the nearest neurosurgical consultant by telephone ? Initially because of a paucity of neurosurgical beds in Bristol, we instituted a system of "vetting" by a consultant, or perhaps a senior registrar, of all cases referred for admission to the neurosurgical unit Judged by the results, the system has worked well in the interests of the patients

It may be asked, can a case of head injury be provisionally assessed on the telephone ? It certainly can, as experience shows This stems from the fact that diagnosis is based on signs which can reliably be described state of consciousness, pupils, reflexes, and so on, and particularly the chart readings, of which pulse and respiration rates are the most important We have encouraged the practice of fifteen-minute readings for the first two hours, then half-hourly, then hourly, so that the trend of the case may be the more quickly judged, especially if a verbal consultation may have to be sought Where possible the patient should be brought to the neurosurgical "base"—not so much for operation as for observation if diagnosis is in doubt, and so that he can be seen frequently, if need be, by the specialist surgeon in the tricky postoperative days The surgeon may have to see his ill patient several times a day Secondary operations are not uncommonly required and often with very short warning

The practice of obtaining expert advice should eliminate the risk of a death in the ambulance Concerning casualty departments and cases of head injury, a safe rule was in force in my former medical school—admit everyone with a history of unconsciousness, even if very brief The beds were found, despite very large waiting lists

THE RELATION BETWEEN SMALLPOX VACCINATION AND POLIOMYELITIS

SIR,—Dr MacIver[1] found that of 35 cases of poliomyelitis in children aged $3\frac{1}{2}$ years or less, only 2 showed evidence of vaccination in infancy He emphasised that written records can be fallible and that all these children had been examined for an actual vaccination scar Our own survey,[2] which showed 29 vaccinated children among 34 under 5 years who had had paralytic poliomyelitis, was a "backward investigation" covering the years 1951–55 It was based on the records, because we could not get visual evidence in a number of the children who had left the area since their illness But in view of Dr MacIver's emphasis on the importance of evidence of a scar, those children in our survey who are still available in the area have been examined Of the original 29 vaccinated polio myelitis cases and 23 vaccinated controls, 19 cases and 17 controls were seen Vaccination scars were confirmed in 18 cases and in 17 controls In only 1 case was there no definite visible evidence of vaccination

While we did not claim that the results of our survey were statistically significant, the check against visible evidence supports the original findings It is also satisfactory that within this admittedly small field of inquiry the accuracy of the written records is sustained

During 1956 there have been few cases of paralytic poliomyelitis in this division Of the 8 cases among children below school-age, inspection of the arm shows that vaccination had been successful in 5 This additional evidence supports our previous view and does not confirm Dr. MacIver s findings , but we hope nevertheless that he will continue to keep records of the vaccinal state of children who contract poliomyelitis and will also compare them with suitably selected controls

Since we last wrote, we have seen the results of an investigation undertaken in Vienna by Dr F. Puntigam and Dr K Berger.[3] Examination of the records of 121 children aged 1–4 years who suffered from poliomyelitis between 1951 and 1955 showed that in Vienna (as in South-East London) there was no statistically significant difference in the incidence of the disease among vaccinated and unvaccinated children

CARDIAC ARREST

SIR,—By his Hunterian lecture in January, 1956, Mr B B Milstein has contributed greatly to the problem of the management of cardiac arrest, and his letter (Jan 5) shows that he considers that every physician and surgeon, and presumably, therefore, every registrar and houseman, should be prepared to undertake open cardiac massage when faced with such a catastrophe A few comments from one who, in the past, has had some considerable experience of this complication, in surgery other than thoracic, may not be out of place

In 1926 I became resident surgical officer of the General Hospital, Birmingham, and six months after my appointment a new Coroner's Act became law, one clause of which permitted the surgeon, in the event of an inquest into the cause of a death under anæsthesia, to be represented by the resident surgical officer, provided the latter was present at the operation, instead of, as hitherto, having himself to appear in court The result was that, as soon as there was an impending disaster in any operating theatre, I was hastily summoned in order that I should be present in case the worst should happen.

This was in the days when anæsthesia was very different from the skilful affair it is today—mainly ' rag and bottle no intratracheal tube methods, very primitive gas and oxygen apparatus and almost no understanding of modern methods of general preparation of patients for operation During my three years as resident surgical officer, I saw 30 cases of cardiac arrest At first, I used the methods of management current in the late '20s, when open cardiac massage was generally regarded as the most dramatic and very last thing to be done

At about this time, Dr W B Primrose, wrote a paper[4] stating that, unless the heart could be started within three minutes, irreversible changes would develop in the central nervous system, and this is just what my own short experience had shown So far as I am aware, this was the first paper to bring to the notice of surgeons and anæsthetists the significance of this absolutely fundamental time factor, and it had an immediate effect on those most likely to be involved on these occasions From then on, we set about direct heart massage as soon as the anæsthetic had been withdrawn and a clear air way assured

However, in those days there were no thoracic surgeons, and certainly no heart surgeons it was the general surgeon who faced these crises, most often in abdominal cases but by no means always so It was not unnatural, therefore, that the popular route for direct cardiac massage was through the under surface of the left diaphragm. If not already open the abdomen was rapidly entered through an upper left mid-rectus incision A further incision, through the left half of the central tendon of the diaphragm into the pericardial cavity, was then made with a knife held with the forefinger along the back of the point, and the thumb and middle finger protecting all but the terminal half inch of the cutting edge The first two fingers were then slipped into the pericardium and around the heart, which was massaged between them and the thumb (which remained below the diaphragm) at a rate of about 60 per minute In 6 of the above 30 cases the heart was re started by this technique and the patients made a complete recovery Of the remainder, in well over half the heart was re started but the patients did not survive, either because spontaneous respiration was not established, or because the heart stopped again and could not be re started, or because, although spontaneous respiration did start, changes in the central nervous system developed and the patient failed to recover consciousness and died within seventy two hours in spinal rigidity and hyperthermia I can vouch for the fact that the heart had indeed stopped in all 30 cases In those days we had not learned to differentiate between "cardiac arrest" and "ventricular fibrillation", but I can recall how on occasions, when I first put my fingers on the left ventricle, there was a sense of vibration, like touching the neck of a purring cat, presumably due to fibrillation, whilst on other occasions, I gained the impression of a completely inert bag After three or four firm compressions a spontaneous "kick" could be felt, and with a few more compressions regular beating would continue When the heart was slow in starting to beat, or failed altogether to start beating, firm regular massage by this route produced a palpable pulse at the wrist and in the carotids, and therefore an adequate cerebral circulation

---

[1] MacIver, D *Lancet* 1956, ii 683
[2] Chalke H D Clark F L *Ibid*, p 545
[3] Puntigam F Berger K. *Wien klin Wschr* 1956, 106, 412
[4] *Brit med J* 1935 ii, 540

I had occasion to massage the heart twice during Army days in the late war, one patient recovered, but the other died as a "spinal animal" Since then I have had to apply massage in 2 further cases, neither patient recovered, though on both occasions spontaneous action of heart and respiration were restored

Nowadays, with modern ancillary services, and especially with good anæsthesia, the general surgeon encounters these occasions less commonly than does the thoracic surgeon, and the latter, having the chest open, will naturally apply massage directly Since surgery of the heart has been developed, it would seem that ventricular fibrillation has become much commoner The heart in arrest can be re started by massage, the heart in ventricular fibrillation is much more difficult to resuscitate, and often requires electrical defibrillation It is fibrillation, it seems to me, that makes the difference between the thoracic and abdominal approaches, since the defibrillator pads cannot be applied through the diaphragm Because "arrest" and "fibrillation" cannot be differentiated until the heart is exposed to sight or touch, I think general surgeons must persuade themselves that the thoracic approach is preferable—though admit that, were I faced with the need during an abdominal operation, I should proceed from below

One final remark although Mr Milstein's letter suggests that the technique of thoracotomy for cardiac massage can be mastered by all, the question does arise—how junior a resident might be expected to undertake this procedure if no more senior person happened to be available? I think it depends on his experience, should he be serving on a thoracic firm, or have seen cardiac massage performed previously, he would obviously be in a better position to try to rescue the situation Yet I do not consider that a man should be blamed for not making the attempt if by temperament or lack of experience he does not feel competent to do so The question is important from another point of view, occasions have happened when, in a coroner's court subsequently, a pathologist has expressed the opinion that such an attempt by a relatively young man should not have been made I regard this as a most unfair criticism for anyone to make who himself is never likely to be faced with such a crisis

F A R STAMMERS

FLUORIDATION A MISQUOTATION

SIR,—In a pamphlet from California entitled "Fluoridation Unmasked" the following statement about myself appears

> "Professor R A Peters, Biochemist of Oxford, England, says 'Fluoroacetic acid prevents the body from breaking down the citric acid created when sugar is burned into simpler compounds Retention of waste citric acid acts as a violent poison on heart and nervous system Fluoroacetic acid is used by African natives to murder their enemies What will happen to the person drinking fluoridated water when he uses vinegar?' (acetic acid)"

I do not know upon what writing of mine this is supposed to be based, but I think it as well to point out that it gives entirely the wrong impression Inorganic fluoride acts completely differently in the body from fluoroacetic acid, in which the carbon is linked firmly to the fluorine Fluoroacetic acid is a rat poison which is much more toxic than fluoride The suggestion in the last sentence that fluoride and acetic acid will combine easily to form fluoroacetic acid is very wide of the truth It is in fact quite difficult to synthesise fluoroacetic acid, and certainly there is no evidence that it can happen in the body, furthermore, acetic acid (vinegar), if given early enough, is an antidote to fluoroacetic acid poisoning in some animals

PROLONGED PYREXIA IN CHILDREN

SIR,—The answer to Dr F E James's problem (Jan 19) is probably brucellosis, despite his careful investigation He has apparently ruled this diagnosis out because the outbreak appeared more like an upper respiratory infection, and because in one case the agglutinations were negative The first reason is not an adequate one Brucellosis often presents as prolonged "influenza," which does not respond to sulphonamides or penicillin A good example of a similar outbreak was given by Elkington et al,[1] and I have seen a minor epidemic near here

The negative agglutination has been the downfall of many a physician, and it cannot be too often or too strongly emphasised that a negative agglutination test does not rule out brucellosis Harris[2] goes so far as to say "In the chronic phase of brucellosis the finding of a positive blood agglutination reaction in a significant titer is the exception rather than the rule"

Apart from this, the histories are suggestive the continued low grade pyrexia, the lymph glands in the posterior triangle, and the reference to tiredness and lack of energy Without any prior knowledge, I venture to guess that the milk-supply at the time was raw (possibly from tuberculin tested herds, but not pasteurised), and that among the people who drank it there were several with prolonged fever, headaches, constipation, lassitude, irritability, and perhaps later rheumatic or neurological symptoms It may be too late to detect the organisms in the milk, but a diagnosis could be made in the patients even now The next step is a brucellin skin test, which is similar to the Mantoux test If it is positive, it shows that the patient has at some time been infected with brucella It has, however, a higher proportion of negative results than the Mantoux After that, the agglutinations should be repeated to see if there is a rise in titre or a change from negative to positive This rise may take place about the second week after the skin test, or it may be delayed for four or five weeks It is possible that a more reliable answer may be obtained if search is made for blocking antibodies and Coombs antibodies (Bürki and Fey[3]).

REFLUX ŒSOPHAGITIS

SIR,—Your leader last week is full of interest. We note with regret, however, that of thirteen references to the literature all but one are American and that you have omitted articles which appeared in your own journal on this subject over our two names in 1955 and 1956.[4]

In these two communications we recognise a point to which your leader refers—namely, the importance of digestive juices other than gastric in the production of œsophagitis. We also suggested a method (Roux-en-Y) of avoiding this sequel to operation.

In the operation we described, the rapid emptying of gastric remnant is essential to success, and we should like to take this opportunity of drawing attention to the fact that we now make an antecolic gastrojejunal anastomosis. Previously we drew the jejunum through the mesocolon, but we have reason to believe that this may cause some obstruction. The more anterior arrangement lies comfortably. Passage of the jejunum through the mesocolon near the splenic flexure seems very liable to be followed by a certain amount of fat necrosis, which may prove very troublesome. We intend to make this the substance of a further communication.

CHARLES WELLS
J. H. JOHNSTON

THE FUTURE OF NURSING

SIR,—May I as a nurse ask your readers not to regard either the tone of Miss Margaret Lamb's letter last week or certain statements in it as characteristic of the outlook of the nursing profession.*

The last paragraph, which suggests (if I follow its meaning) that the standards and code of ethics of nurses have nothing to do with and are not the concern of the medical profession, seems to me to call for a disclaimer on our part.

As I, and I hope many other nurses, see it, the trained nurse acts in a dual capacity. First, she assists the doctor by carrying out the treatment he requires for his patients (using the word "treatment" in the widest possible sense), and by giving him the results of her expert observation of his patients, since her contact with them is much less intermittent than his. Secondly, she uses in the service of the patients her own skills, which include much not normally the concern of the doctor—important details of basic nursing care, and the maintenance of a therapeutic environment (which should include such amenities as quiet, order, fresh air, and flowers or other pleasant things to look at), and if she acts in a senior capacity she should be the twenty-four-hourly coördinator of the now almost innumerable services provided for the patient—from catering to religious ministrations, from pathological-specimen taking to visitors, from physiotherapy to floor polishing, from voluntary helpers to social surveyors. In domiciliary nursing the nature of the duties may be different, but the need for coördination is no less great. Without this coördination the patient is liable to be exposed to chaos. The nurse cannot secure it unless she is wise enough and tolerant enough to realise that all have a common aim, to show that she respects the contribution of all who serve the patient, and to keep herself free from the professionalism run riot which so easily infects certain groups.

The nurses' high privilege of being the only ones on whom the patient depends for constant care all round the clock should make it easy for them to accept that it is ultimately the doctor who is in charge of the patient. Although the ward sister, for instance, has lines of responsibility directly to her medical staff and another to her matron as professional head of the nursing service, the fact that conflict between these responsibilities is so remarkably rare suggests a true partnership, in which the nursing profession willingly assists the medical profession, but both make also their individual contribution to the well-being of the patients.

This could not but suffer if nursing became an entirely independent profession with differing standards and ethics, and a training in which doctors take no part. One can only suppose that those who put forward such suggestions have not fully thought out the implications.

King Edward's Hospital
Fund for London,
Division of Nursing,
21, Cavendish Square, W.1

MURIEL M. EDWARDS

SIR,—As a nurse who has for the past thirty years been actively concerned with the training of nurses, may I try to sum up the situation which concerns many at the present time? As I see it, we require three groups in the nursing profession.

(1) A small group, highly trained and with great ability, to plan future progress, to negotiate with the appropriate Whitley Council, and to represent the profession at Ministerial level and on important bodies when nursing opinion should be expressed. It is for the benefit of members of this group that some advocate the institution of a university degree in nursing. While the value of this is debatable, none will deny that a trained mind is of great importance in those who aspire to lead their profession.

(2) A large body of nurses who are capable of fulfilling all the needs of the sick—a far wider requirement than bedside nursing care, important although this is—who can give intelligent assistance to their medical colleagues, who are wise in handling and capable of teaching student nurses, and who by word and example can guide the public on matters of health and hygiene.

We expect much of our nurses, and our methods of training in the past have met with some measure of success, if we may judge by the regard of patients, and by the esteem in which British-trained nurses are held in many countries overseas.

That the training needs constant consideration, and frequent modification to meet changing conditions, is fully realised by the General Nursing Council, which includes medical and educational representatives, but reorganisation must be undertaken with great care, lest a retrograde step causes the loss of much of the progress made during the past century.

(3) There is unquestionably need to give every opportunity to many who for various reasons are unable to meet the full demands of training for State registration, and yet have real gifts of nursing. Assistant-nurse training is still in its infancy, and both nurses and doctors can do much to overcome the ignorance which at present delays the full acceptance of this grade as an essential and invaluable part of the nursing service.

Strong representation has long since been made to the appropriate Whitley Council both to give equal consideration to those engaged in assistant nurse and in State registration training, and also to approve a grade of "senior" assistant nurse. Early recognition of these principles would help considerably to give the assistant nurse a full and honoured place in the health team.

With such varied requirements and faced with candidates of widely differing ability, it is hard to envisage one basic training likely to give equal opportunity and satisfaction to all, and although theoretically such a scheme has much to commend it, in practice we might well lose many of the very students whom we are most anxious to attract.

For the present I would choose rather to see a more careful selection of students with guidance of each individual into the type of training likely to give the fullest satisfaction and benefit to all concerned.

---

[3] Bürki, F., Fey, H. *Schweiz. Z. allg. Path.* 1953, 16, 91.
[4] *Lancet*, 1955, i, 937; *Ibid*, 1956, ii, 479.

Finally may I reaffirm my view that 18 years is the minimum age at which the average student should be expected to face the physical, mental, and spiritual strain which training in a general hospital imposes, and which can perhaps only be fully understood by those who have taken such training, also that the State registered nurse, after three years' training, is still very young at 21 to accept the heavy responsibility which qualification brings

The conflicting requirements of the sick patient and of the student nurse present perhaps the greatest problem with which the nursing profession is faced at the present time, and this emphasises the need to encourage the appropriate training and full use of all who can participate in this essential service

Addenbrooke's Hospital,
Cambridge

L J Ottley

RECURRENT MOTOR PARALYSIS

Sir,—The following case appears to us to be unique

A girl, aged 6 years, was first seen by one of us (G E B) at St John's Hospital, Uxbridge, on March 23, 1956 She had been sent in as a case of poliomyelitis because she was "dropping things" and her arms and hands were weak There was an indefinite history of frontal headache and pains in the elbows during the previous weeks but no fever or meningism On admission she had hypotonia of both arms with bilateral weakness of the shoulder girdle, triceps, biceps, and extensors of the wrists No sensory changes were detectable Lumbar puncture yielded a normal fluid, a blood count was normal, as also was the serum potassium There was no porphyrinuria

The child made steady progress and on April 25 was discharged home, but, as there was some residual weakness of the right deltoid and the extensors of both wrists, she was to attend a nearby hospital for physiotherapy Eight days later, on May 3, she was admitted to this hospital as an acute respiratory emergency. This time she was moderately febrile There was complete diaphragmatic paralysis, with weakness of swallowing and of the voice and hemiparesis of the soft palate (left) and of the tongue (left) There was also right facial paralysis and generalised weakness of all four limbs On admission her vital capacity was only 400 c cm As this decreased to 300 c cm within an hour, tracheotomy was performed and a cuffed endotracheal tube was inserted as a preliminary to intermittent positive pressure ventilation The improvement which resulted from these procedures, however, was such that her intercostals supplied her needs and she was not in fact mechanically ventilated Intragastric feeding had of course to be instituted Subsequent progress was slow but steady On May 22 the tracheotomy tube was removed and by May 25 she was swallowing satisfactorily, her voice had become much stronger, and her vital capacity had increased to 800 c cm Power was also returning to her limbs and she was allowed up

On June 19, however, the right facial palsy, which had fully recovered, recurred, and fears were entertained that a further bout of paralysis might ensue Fortunately, these were not realised and by July 2 her vital capacity had increased to 1040 c cm although her cough was still poor

By July 17 she was walking well and the right facial palsy had, for the second time, almost recovered There was still, however, poor dorsiflexion of the wrists and a tendency to bilateral dropped foot Her tendon reflexes were just present and equal in all four limbs No sensory disturbance was demonstrable at this—or any other—time apart from some slight loss of vibration sense at the left external malleolus She was accordingly discharged home on July 17 and asked to return periodically for observation

She remained well at home until July 28 when she complained of pains in her legs and her walk became unsteady A week later the rash of chickenpox (to which she had been exposed by her cousin) appeared, and simultaneously a marked weakness of the left side of the face was seen Readmitted on Aug 4, she had no other cranial nerve palsy Chest movements were good and the diaphragm was acting normally, although her cough was still not very forcible Her limbs appeared to be much as they had been on discharge, although, while the upper arm tendon reflexes were just present, the knee and ankle jerks were absent on both sides The abdo reflexes were present, and there was again no se loss

The facial paralysis persisted for some days and recovered rapidly Repeated investigations at this showed normal fundi, a normal cerebrospinal fluid, n serum potassium, and absence of porphyrinuria The gamma globulin and pyruvate levels were also no Progress was rapid, and dorsiflexion of the wrists be strong at last though there was still slight bilateral dr foot She was discharged on Sept 8, since when she has seen several times She is in good health, intelligent, and cheerful with very slight residual weakness of th side of the face and of the limbs

Here then is a child who, within five months, sust four separate episodes of motor paralysis invo (1) both upper limbs, (2) the diaphragm, the pha the larynx, the left tongue, the left side of the palate the right face, (3) the right face, and (4) the left To what can these recurrent palsies have been due seems very unlikely to have been an infective a To begin with, fever was absent during the first ep and only slight at the onset of the second, was a during the third, and during the fourth was due prim to the chickenpox There was no meningism at time, the cerebrospinal fluid was normal throughou also was the blood count Again, in view of the no gamma globulin, it is hardly conceivable that, after a severe challenge to the defences as was sustained i second episode, antibodies would not have appear sufficient titre to ensure immunity for months, if no years

The alternative is an error of metabolism (analo perhaps, to migraine) producing some toxin or defic with a selective action on the lower motor neur Efforts were made to discover whether any parti drug or article of diet could have been respon When the right facial palsy recurred on June 19, she still in hospital under observation and close inquir all conceivably relevant factors was made The suggestive fact was that, a few days previously, she been given phenolphthalein as a purgative—at mother's suggestion, because she had been accusto to it at home The mother was advised that this better be avoided and she was not given it again A final episode of facial palsy coincided with the ons chickenpox, it is tempting to connect the two, but was no evidence of encephalitis or of geniculate herp the only ways, in our experience, in which the vari zoster virus affects the facial nerve

We should be interested to know if any of your re has encountered a similar case Moreover, as the pa returns for periodic observation, we would welc suggestions as to any further investigations that m in retrospect, usefully be made

VIVA-VOCE EXAMINATIONS

Sir,—It is generally agreed by psychiatrists that unconscious transference of the emotions of love hate between patient and therapist is the most po factor in the psychotherapeutic interview It is not in psychiatric treatment, however, that this phenome plays an important part, and even statesmen w do well to recognise its importance in their dealings each other

There is one aspect of this matter which serio affects recruits to the medical profession in viva examinations The candidate is inevitably in a s of nervous tension, and under these conditions a powe transference situation arises between examiner examinee So often a candidate will pass in his pa and fail in his viva, not through lack of knowledge, by this unconscious factor which interferes lamentably with his self-confidence

Since failure may result, today, in his having to give up a medical career after having spent several years and much money on a medical training, it would seem very unjust that a possibly brilliant career should be jeopardised by such an irrational element Would it not be possible, in cases where this occurs, for the candidate, having passed his paper, to appeal against the decision of the viva voce examiner, and be given a second chance by another examiner ?

Bath E R **MATTHEWS**

VAGITUS UTERINUS

SIR,—I can add another case to those enumerated in Mr Russell's interesting article last week I did not report it at the time as I thought that the existence of the phenomenon was unquestioned

In this case, when I was resident obstetrician at Park Hospital, near Manchester, I was scrubbing up to do a forceps delivery on a woman who had had premature rupture of the membranes I am unable to recall the indications for forceps delivery, but the woman had only had vaginal examinations and no manipulations Suddenly the uterine cry of the baby was heard by myself, by the anæsthetist, by the sister in charge, and by the staff nurse It was repeated on a number of occasions, and when delivery was effected the baby continued to cry lustily during the extraction as well as immediately afterwards No ill effects were observed on the baby, whose cry in the uterus was quite strong and could be heard distinctly by me standing several yards away scrubbing up at the time

Manchester B **SANDLER**

SIR,—Mr Russell's article reminds me that several years ago, when I was in private practice, I was puzzled by the fact that in a primipara with an apparently normal left occipito anterior position the membranes ruptured two weeks before delivery

When she went into labour I found that one of the child s hands was at the side of its head, and causing obstruction Manual replacement having failed, and no progress being made, I decided to apply forceps as the cervix was well dilated Then it happened ! At 2 A M in a silence that could be felt, a distinct muffled cry occurred coming from the mother s abdomen I turned to the maternity nurse, and her normally rubicund face was ashen with shock

A perfectly normal forceps delivery followed, and the child cried at once, with no ill effects

MEAN VENOUS PRESSURES IN THE FIRST HOURS OF LIFE

SIR,—We are indebted to Dr Brown (Jan 19) for at least two reasons His letter gives us a chance to acknowledge the work of the Oxford physiologists, G V R Born et al,[1] and it will bring this excellent work into greater prominence in medical circles We did know of it and perhaps should not have been so species specific Dr Brown's letter also gives us the chance to emphasise the oddity in our paper This is not that the venous pressures in the fatal cases were "low" (they fell in fact within the normal range) but that the survivors' pressures were "high"—i e, over 5 cm dextrose solution If we might amplify this a little further without too much speculation, we would like to do so by commenting on Potter's phrase "pulmonary congestive failure"

A circulation can fail because the propulsive power of the heart diminishes because the vascular resistance to this propulsive power becomes too great because there is not enough blood to pump round, or because of combinations of these The Oxford group have shown in lambs the great increase in vascular resistance in the pulmonary circuit caused by asphyxia, we do not yet know what the vascular resistance is in normal unexpanded human lung, but it is possibly high To overcome this and any increase due to asphyxia it is possible that a high cardiac output dependent upon a high venous pressure is necessary Many serial readings in both groups were done but were not included because of the possible effects of therapy They showed in general that in the survivors the pressure returned to normal levels with clinical improvement within 12 hours and in the fatal cases did not rise except in one as a terminal event after 30 hours

A SIMPLE SELECTIVE TEST FOR NURSES

SIR,—I accept Dr Haward's explanation (Jan 5) that his test was offered as a supplement, and I agree that these are early days for nursing selection techniques Nevertheless, one cannot help being mildly suspicious of its apparent intention to measure "scholastic ability"—a supplement at that If it is ever to be put forward as a test "par excellence," then it should attempt, even at this early stage, to measure concentration as a separate factor

Dr Haward asks me what I mean "by requesting a correlation for *each* student ?" I will merely say here that on occasion I have found students who though they could not give suitable written answers to questions, could dictate "excellent" answers Such cases justify my previous criticism of Dr Haward's test, that it does not attempt to measure "writing fluency"—an important consideration An intelligence test is the better alternative in *such cases*

Runwell Hospital,

X RAYS AND LEUKÆMIA

SIR,—My letter of Dec 15 was prompted by a consideration of the practical steps which radiologists would have to take if they accepted Dr Stewart's findings Perhaps it may help to restate the problem Dr Stewart's results have, for the first time in the history of radiology, suggested that a very small dose, hitherto regarded as absolutely safe, may be harmful If, in fact, a dose of 1r (to a fœtus or adult) can cause leukæmia in later life then we must revise our view that a dose of 0 3r per week for every week of the working life of a radiographer or radiologist is harmless Radiation doses are cumulative, therefore a dose of 1r every three weeks or 16r every year has been permitted for an X-ray worker A whole-body dose of well over 200r during a working life has hitherto always been considered safe On Dr Stewart's figures, we are jeopardising the lives of all who work in diagnostic departments, because it is impossible to keep the radiation scatter dose below 1r in, say, ten years without rebuilding every diagnostic department and without stopping all screening

I therefore examined Dr Stewart's report in the hope of finding a simple explanation for her surprising results The figures are entirely based on statistical not on clinical considerations The word "routine" on an X-ray form has been interpreted as meaning that the patient is perfectly fit, but to a radiologist or obstetrician it indicates that there is suspicion of either a fœtal abnormality or some maternal disease

In my experience a pregnant mother is never referred for an X ray examination unless there is some definite suggestion of either maternal or fœtal abnormality, but this is seldom mentioned on the form because that is usually handed to the patient

Moreover Dr Stewart does not explain why 15 more of the leukæmia mothers had non abdominal X ray examinations than did the mothers in the control group before conception of the survey child The total excess of X-ray examinations on leukæmic babies over normal controls is only 18, and it is on this figure alone that the whole of Dr Stewart's argument is based Both sets of figures may be of equal importance, and the only way in which they can be explained is by stipulating a pre existing morbid factor, in either mother or fœtus, which predisposes to the later occurrence of leukæmia

---

[1] Born G V R, Dawes G S, Mott J C, Widdicombe J G *Cold Spr Harb Symp quant Biol* 1954 19 102

Dr Court Brown and Dr Doll, in their very interesting reply (Jan 12) to the points I raised, state that 20,000,000 people will have to be exposed to a mean marrow dose of 1r in excess of that received by the general population and observed for ten years before it can be decided whether or not a dose of 1r can be responsible for leukæmia This may be the statistical ideal, but it does not seem feasible to apply such a method in practice

In the consideration of low-level radiation effects, however, the data which we possess on the general incidence of leukæmia are most helpful Natural atmospheric background radiation received by every human being amounts to 0 1r per year Therefore, after ten years, everybody has been subjected to 1r, and after a lifetime of seventy years, to 7r If small doses of radiation are a cause of leukæmia one would expect, on statistical grounds alone, that as dose increased with age so would the incidence of leukæmia, and, in fact, this is not so

Dr Court Brown and Dr Doll consider that the present evidence does not justify the belief in a threshold dose of between 100 and 200r, but they have not been able to adduce a single fact or experiment in which it has been proved that a low dose of radiation was leukæmogenic To their comments I should like to make the following points

(1) They attribute the absence of leukæmia in the offspring of pregnant mothers in Hiroshima to shielding by buildings I gave the figure of 1500r as a maximum dose to which some had been exposed The fact that so many of them developed severe radiation injuries indicates that they must have been exposed to many hundreds of r While these women had many abnormal children, especially micro cephalics, none of them developed leukæmia within nine years of observation [1]

(2) I suggested that among the survivors of Hiroshima and Nagasaki beyond a distance of 2000 metres, doses of 100 or even 200r must have been common because so many people had radiation sickness Dr Court Brown and Dr Doll think that this may be the malaise, with nausea, vomiting, and diarrhœa, induced by physical and emotional stress I am convinced that the very careful investigators of the Atomic Bomb Casualty Commission would not have classified these cases as due to radiation if they had been of psychological origin I cannot remember similar symptoms in people exposed for months on end to the stresses of air raids in this country But even if the total exposure dose received by the 155,000 people was only 8r at a distance beyond 2000 metres, that still confirms my original contention that such a dose was inadequate to increase the normal incidence of leukæmia If Dr Stewart's argument is correct, then even this low dose would have raised the amount of leukæmia considerably beyond the normal limits Yet the incidence among the very large number of exposed people remained roughly within normal limits [2]

(3) In quoting the figures collated by Dr Court Brown and Dr Doll on the radiation treatment of ankylosing spondylitis, I intended to give further support to my argument that all recorded cases of post radiation leukæmia were caused by large doses—in this case, doses of at least 400r

(4) I fully admit that the course of leukæmia in animals after irradiation [3] is not exactly comparable to that in human beings Nevertheless it seems unlikely that man is 100 to 200 times more susceptible than a rat, or that a dose of 1r produces leukæmia in man when 2500r is needed in dogs Experiments have proved that a small dose must be repeated many hundred times in every kind of animal before a tumour develops With a daily dose of 0 1r at 250 kV it was not possible to produce leukæmia in rats however many doses were given With 0 5r daily at 250 kV, 225 and 491 treatments had to be given before leukæmia occurred in 2 animals With 1r daily at 1000 kV, it was impossible to induce leukæmia in any of 42 rats Though animal experiments were not primarily designed to investigate low level radiation the fact that leukæmia could not be induced with these doses suggests that a fairly substantial dose is, in fact needed to produce it [4]

I am glad that radiologists, such as Dr Brailsford (Jan 5), with many decades of experience have confirmed that they have never seen a case of leukæmia which could be attributed to a diagnostic dose of radiation

For practical purposes the risk to the fœtus (even assuming there is one) seems so small as to make it desirable to counteract the erroneous impression created among the general public by the preliminary results of the investigation At present, when the recruitment of radiographers is becoming increasingly difficult an official statement by the Faculty of Radiologists on the lack of evidence that small doses of radiation are harmful might be appropriate

London, W 1 J RABINOWITCH

Medicine and the Law

The Duty of Care

IN a case at the Glamorgan Assizes before Mr Justice Sellers the duty of care owed by a hospital committee for the state of the hospital premises was under scrutiny

The widow of a patient claimed under the Fatal Accidents Act 1846 for herself and under the Law Reform Act 1934 for her husband's estate The husband, aged 59, a diabetic for many years, had returned home early from work feeling dazed and giddy He was admitted to hospital in the afternoon to a general male surgical ward and seen by the sister and doctor who made routine examinations Next morning, apparently very cheerful as usual, he went to wash and to the sluice room A few minutes later he was found dead in the yard beneath a corridor window The window was open and there was some scraping on the brickwork below It seemed clear that he had fallen, but there was no reliable evidence as to whether the window was open before he went along the corridor, or information as to who had opened it

According to the medical evidence called for the hospital it seemed that the possibility of a prediabetic coma producing uncontrolled swaying in this man was slight, and that the duty owed must be seen as that owed to a general ward patient In giving judgment for the hospital the judge based his conclusions on the foreseeability of the event happening If the reasonable man could have foreseen that this accident was "on the cards" and that to prevent it steps ought to have been taken to make the windows secure, and these steps were not taken, the hospital might have been liable in negligence But this was a corridor window, the sill 2 ft 3 in from the ground (its total depth 15 in) and the lower sash opened to 2 ft Nothing unusual had been observed in the conduct of the patient to make extra precautions necessary, and allowing the patient to move about was a feature of treatment, in that maximum freedom of movement was desirable For young children or mental patients extra precaution seemed clearly necessary, but it appeared to be unreasonable and even undesirable to restrict the amount of air and the sense of freedom available in the hospital The widow had admitted that, though she and her family tried not to leave the deceased alone in the house, he might well be upstairs on the first floor alone, and no blocks had been fitted to the windows The position there seemed to be parallel to the state of affairs in the hospital

[3] Medical Research Council Report Cmd 9780 H M Stationery Office, 1956 p 87

[4] Metcalf, R G, Inda F A *In* Biological Effects of External Radiation New York, 1954

There was one other feature In 1954 a patient had apparently committed suicide by jumping through a window at the hospital, and blocks had been fitted by order of the committee responsible so that the window opened to no more than 7 in On the painting of the frames the blocks were removed from this and other windows and there seemed no clear evidence as to why the blocks on this window had not been put back The question then arose—had the hospital set itself a standard of care in supplying blocks, the removal of which by some servant of the hospital and the failure to replace by a relevant authority, had provided the required incident of negligence? His Lordship did not accept this as a test, and applied clearly the test of reasonable foreseeability so that, to avoid the situation whereby the hospital authorities became insurers, the defendants were held not liable to the widow The floor was in a good condition and the height and width of the ledge made it improbable that the man could have fallen unless already part projected through the window frame It was difficult to see what blame—since fault and breach of duty must be seen in this tort—could be cast upon the hospital committee or its servants for an incident which could not reasonably have been foreseen as likely to happen

"Truth Drugs"

Narcoanalysis is a legitimate and valuable technique in psychotherapy, though it is true to say that the barrier to repressed material can often be raised by analytical methods alone If drugs are used their main advantage is to speed up the process But when the information that is sought is being held back by conscious suppression of guilty knowledge, drugs seldom release it Most of the evidence suggests that voluntarily suppressed matters are rarely revealed under narcosis, and that "truth drugs" are useless in police inquiries Indeed, a guilty person may, under narcosis, manufacture evidence to suit himself, or what is worse, devise fantasies involving himself in crimes he has not committed Moreover, the suggestible neurotic or psychopathic criminal can be made to say almost anything These and other objections to evidence obtained under the influence of drugs were well brought out at a meeting[1] of the Medico-Legal Society.

Even if there were a drug that could unlock the truth, statements made under its influence would clearly be inadmissible in a court of law First it is a fundamental legal principle that a statement must be made voluntarily without threat, duress, or other influence Secondly, the statement would have to be read by the doctor who administered the narcosis or someone other than the accused and that would make it hearsay and therefore inadmissible The principle at the root of the British exclusion of hearsay evidence is the absence of the oath It is clear that a man deprived of his senses cannot swear to speak the truth, and when he regains full consciousness he is at perfect liberty to say that his statement under the drug was nothing but a product of delirium and without a vestige of truth

Only a qualified doctor should induce narcosis—yet few would be prepared to do so for reasons other than medical treatment Indeed it is hard to imagine a more striking breach of the Hippocratic oath than the use of medical skill to obtain evidence that will lead to a prison sentence Moreover the doctor concerned would have to be called by either prosecution or defence, thus immediately seeming to show partiality and the doctor could quite fairly, be charged by the other side with the manufacture of evidence by suggestion—a charge which would be hard to refute

Obituary

ERIC BARRINGTON BROOKE

M.A, M B Camb, F R C.P, D.P.H

GERIATRICS is one of the youngest of the specialties, and by the death of E B Brooke it has lost one of its pioneers His work at Carshalton and later at Southampton was a memorable demonstration of how much can be achieved by personality in administration

Dr Brooke was educated at Bradfield College, Cambridge University and St Bartholomew's Hospital After qualifying in 1923 he held house-appointments at Barts and later became assistant medical officer at St Giles Hospital Camberwell In 1925 he took the D P H and two years later the M.R C.P. The next years he spent at Redhill Hospital Surrey, at first as deputy medical superintendent and then as superintendent But the most important part of his work began with his appointment in 1941 as superintendent of St Helier Hospital Carshalton D D relates how he met the challenge of those war-time days when the buildings under his charge were new and empty and when man-power and materials were difficult to obtain

The patients at St Helier in the early years were a heterogeneous collection — evacuees from London hospitals, air raid casualties and soldiers as well as people from a large area of North Surrey Determined to make the best use of the beds, Dr Brooke kept a close personal watch on all the wards, but he never interfered with the clinical work of his colleagues in other departments Indeed no matter how remotely any new development or change of administrative policy might affect our work he invariably sought our opinions before taking action. With the general practitioners of the area also, he established a friendship and coöperation which they and the hospital staff continue to enjoy His geriatric work grew out of his personal interest in the patients and their doctors, for try as he would the aged sick could not always be admitted to hospital and often had to wait for a bed He worked out a scheme to help them to live more happily at home perhaps after a short stay in hospital for investigation and rehabilitation and his imaginative understanding of the needs of old people led him to bring hospital facilities, laundry services and meals on wheels to their homes so that hospital beds could be freed for more urgent cases

His determination was well exemplified by the way he managed somehow to extricate himself unaided in spite of severe facial injuries, from his house when it was reduced to ruins by one of the bombs that fell on the hospital Returning to work after treatment he would joke about our 'one eyed superintendent' and regale us with stories of the matey people whose company he had enjoyed in the large ward that he preferred to a private one during his short stay at a convalescent hospital The secret of his success seemed to lie in his intense interest in people and his almost boyish sense of humour In the early days he knew all his staff well, from maids to medical specialists and as the work of the hospital grew he still managed to retain this personal touch. His aim was to have a happy as well as an efficient hospital and visitors from many countries whom he conducted round it never failed to be impressed by the atmosphere that he had created

Another of the innovations he introduced to meet an administrative emergency was domiciliary visiting which quickly proved its clinical worth and is now an accepted technique in the care of the aged P McE, who visited St Helier in those early days, describes a domiciliary-visit round on which he accompanied Dr Brooke

With Dr Brooke was his registrar and his secretary First he had a short talk with the relatives, then he investigated the patient Then the relatives, the secretary, and Dr Brooke (or the registrar) went over the whole matter and gave advice and decisions, and the secretary made the necessary notes for the case record It was all simple, easy, free from fuss The procedure had a wonderful effect on waiting-lists, and Dr Brooke was, through his secretary, in constant friendly touch with doctors

Of a hospital ward round J N A writes

Dr Brooke was extremely gentle and considerate both to his patients and to those of us who went (as I did) to learn from him Yet he was an animated and tireless man Going round his wards with him I perhaps got the impression he was not first and foremost a clinician He loved the administrative aspect and the logistics of geriatric work But he was a humanist his patients loved him, and he knew them (450 at a time) almost all by name and background

In 1953 he was elected FRCP By then the empty building that he had taken over had been for several years a very busy general hospital of over 700 beds and had gained an international reputation for its geriatric work But Dr Brooke was not content to stay and watch the results of his work, for he still had the spirit of a pioneer He left St Helier to reorganise a geriatric service in the Southampton area There he followed, though on a wider scale, the principles of administration that had served him so well at Carshalton Broadly speaking, the acute geriatric beds at Southampton General Hospital were used for the clinical assessment and treatment of new patients Those who responded to treatment returned home or were admitted to welfare establishments, while those who failed to do so were transferred to long-stay beds in one of the three outlying hospitals He continued to be a firm believer in the domiciliary visit before the patient's admission to an acute bed and in "half-way houses" for "frail ambulants" before their admission to welfare homes Financial stringencies often frustrated his best intentions, but he lived to see much-needed reconstruction both at Moorgreen and Ashurst Hospitals

Though he was dogged by ill health he filled his professional life with more hours of work each day than most fit men can manage He was a founder member of the Medical Society for the Care of the Elderly and he hardly ever missed a meeting in whatever part of the country it was held He travelled abroad to many international conferences, and he was always willing to help, as counsellor or speaker, when any organisation for old people was being started He was a fluent speaker, a master of the happy phrase, and he delighted in appropriate quotations from the lyrics of W S Gilbert and the poems of A A Milne

Dr Brooke died at his home at Southampton on Jan 13 He leaves a widow and two adopted children

RUFUS CLIFFORD THOMAS

FRCSE, FRCOG

IN 1937 Croydon started a comprehensive obstetric service offering "antenatal, natal, and postnatal supervision under the same specialist obstetrician" and Mr Rufus Thomas, who was already on the staff of the council, was appointed to its charge as assistant medical officer for obstetrics and gynæcology In 1945 he reported in our columns that it covered three-quarters of the births of Croydon, and before he retired in 1948 the scheme had made civic and public-health history as an exercise in cooperation and coordination

He qualified from Westminster Medical School in 1915 and held house-appointments there After serving in the R A M C he became supervisor of anæsthetics in the gynæcological department of Edinburgh Royal Infirmary and later senior anæsthetist to the Royal Gwent Hospital, Newport, Monmouth In 1924 he took the FRCSE He next spent six years in India as chief medical officer to the Maharajah Jamsaheb of Nawanagar (better, if less formally, known to many s Ranji) For his work at Jamnagar Mr Thomas wa awarded the order of merit of the State of Nawanagar In India he continued to make a special study of obstetrics, and soon after his return to this country he joined the staff of the Croydon public-health department, as clinical head of its maternity and gynæcological servic

O M H, who worked with him as MOH of the borough writes

Under a quiet and retiring manner Thomas hid an alert incisive, and analytical mind, eager always to try new ide to formulate his own, and to put his whole personality into ensuring their success He made an ideal head of a compl clinical unit By his clinical skill and dexterity, and h understanding of their problems, he had the respect of t doctors, nurses, and midwives under his direction Nev demonstrative, always courteous and calm, he obtained t unquestioned confidence of those for whom and with who he worked To me, as his old chief, his memory will rema that of a completely reliable and loyal colleague, and a ve likeable and cultured Welsh gentleman

In 1947 he was elected FRCOG, and the followi year he retired from his Croydon appointment und the age-limit He continued to lecture and examine f the Central Midwives' Board and he was consulta obstetrician and gynæcologist to Kent County Council

R G S, one of his surgical colleagues, recalls fir meeting him in 1930 at Croydon

I soon learned to respect both his clinical acumen a manual dexterity He brought to his chosen specialt vast experience in general medicine and surgery, gai largely in India, and his flair for diagnosis evolved part from this and partly from his careful attention to detail a to routine observations He expected the same high standa from his subordinates and inspired them by his exampl In addition to his clinical work he took an active interest many other aspects of medicine, and his sagacity and for sight were of great help to his colleagues on the many com mittees on which he served, often as chairman His enforce retirement saddened him for a while, but, with typical ze he continued with his committee work and found time last to play his beloved golf, a game at which he excelle His other hobbies were fishing and story telling, for he h an apparently inexhaustible supply of anecdotes about t years he spent in India and had a remarkable memory f detail

Mr Thomas, who died on Jan 11, leaves a wido and a daughter

Notes and News

WORLD HEALTH ORGANISATION

THE nineteenth session of the executive board of the orld Health Organisation is being held under the chairman up of Prof G A Canaperia from Jan 15 to Feb 5 in Geneva he proposed budget of $12,048,000 for 1958 represents an icrease of $1,348,000 over the 1957 budget, designed to estore the level of field activities originally proposed for 957 but cut by the World Health Assembly

QUACKS THROUGH THE AGES

In an entertaining lecture to the Royal Society of Arts ast November, Mr A Dickson Wright defined a quack as one who sells a secret remedy" He spoke of many of them, rom the *Apocrypha* to the present century, showing that hey were often favoured by notabilities and the public, lespite the indifferent success of their treatment Oberndorf, n 1602, described "quack-saluers" in language worthy of ir Thomas Urquhart Less harshly, Mr Dickson Wright oncluded that "essentially they are those who choose short uts to the curative art and avoid the trial and tribulation of he long and arduous training in medicine"

VIDIUS

AMID our present vicissitudes we may do worse than look o our past for guidance, and what more pleasant way of doing so than to read, for instance, Dr Brockbank's Thomas Vicary lecture,[1] which he called The Man who was Vidius? Vas medical life more satisfying in the 16th century, or were he frustrations to be met under the patronage of Kings and Princes as withering as any that bureaucracy can offer?

To most of us Vidius is no more than a name to be connected n a vague way with the Vidian nerve Born in Florence when he Renaissance was in full flower, a Greek and Latin scholar with an easy style in the latter language, and fortunate in having family connections with the arts, Guido Guidi (he ater latinised his name to Vidius) was a highly esteemed and uccessful *practitioner* of medicine in his home city before he vent to Paris on the invitation of Francis I in 1542 It was n Paris that he completed the translation from Greek to Latin, with commentaries and additions of his own, of a set of ancient manuscripts containing certain works of Hippocrates alen, and Oribasius *It is on this* book, entitled *Chirurgia* hat his fame rests, the more massive *Ars Medicinalis*, ompleted and published after his death by his nephew, at Guidi's request, contains more of his personal teaching on nedical matters, but only *the* section on anatomy can be egarded as important Even those who cannot read the text of the *Chirurgia* can understand and enjoy the magnificent voodcuts with which it is adorned—some of them being eproduced in Dr Brockbank's paper They are mostly llustrations of *methods* by which forcible traction could be pplied to dislocated or fractured limbs Force was the watch vord levers, screws, the windlass, block and tackle, and gravity were all brought into play, and no doubt force was necessary to overcome the spasm in muscular subjects fully onscious

Whether a doctor's life was better in those days than now nay be arguable but there is no doubt where the patient's preference would lie, for the surgical apparatus of the period despite its humane purpose, bore a striking resemblance o the instruments used for torture

MATERNITY FILM

Birth of a Baby is a re issue of a 17 year old film for cinema audiences which has been modified to incorporate advances U S A 62 minutes)

Mary Burgess visits her doctor, who confirms her pregnancy and hen explains, with the aid of diagrams the physiology of conception and implantation of the ovum He advises her to live normally voiding strenuous exercise and horse back riding On receiving a normal blood report the doctor comments on the rhesus factor which in Mary's case is positive and therefore not incompatible with her baby's blood, and he then tells his nurse that he wishes his patients could have their babies in hospital as do most American mothers now instead of at home Recounting a recent visit to a New York Lying in Hospital we see a group of expectant mothers with their husbands on an antenatal tour of the maternity department and labour wards At parents classes Mrs Burgess attends ectures and demonstrations which are shown in some detail and he doctor comments that those who attend the classes make better patients and happier people Fathers are also encouraged to attend The anatomy of the birth canal and the mechanics of parturition are described briefly with models and, at her final visit to her doctor before the delivery is due, Mrs Burgess listens to her baby's heart through a stethoscope Finally the delivery at her home is shown briefly, silver nitrate being dropped into the infant's eyes, and the film ends with an account of the advantages of breast feeding

Rhesus negative mothers might be unduly alarmed until they can discuss the film with their doctors, and references to "anæsthesia during labour, but you will be awake to see your baby born" give a muddled impression Technically the film is bad, the retained portions of the old film, showing the age and dress of the characters seventeen years ago, is mixed haphazardly with modern shots, the contrast in photographic quality and sound recording accentuating the differences The film is unlikely to cause the sensation it did when first shown publicly in this country

TRAINING OF THE DISTRICT NURSE

WHEN the working party on the training of district nurses presented its report, we expressed concern at the recommendation by the majority that the period of training should be cut[1] We hoped that the minority view would prevail, and that the period would remain that recommended by the Queen's Institute of District Nursing The report was discussed at a meeting of the Queen's Institute later that year,[2] when the proposal to shorten the course found no support The differences in technique and approach between home and hospital nursing, and the time needed to learn these, were emphasised

A revised syllabus[3] has now been published The lectures have been increased in number and changed in emphasis to accord better with modern needs, but the period of training is to be as long as it was before—i e, six months for State registered nurses without special qualifications, and four months for those who are also midwives, health visitors, or tutors, or have had at least eighteen months' experience in district nursing

---

University of Bristol

On Jan. 18 the following degrees were conferred

M.D—D R Coles C H Gurd, Lisa E Hill Roy Hill
Ph D (in the faculty of medicine)—Syed Murtaza Ali Zaidi

University of St Andrews

At a recent final examination for the degrees of M B, CH B, the following were successful

L. M. Aitkenhead, L R Butler-Manuel D C Crawford, R A Haddow, Philip Hossen, M. J Illingworth, *D W Jervis, J L Maddison J P M. Penney D J Sutherland, *T T Thompson, H E G Thomson, Elinor M. Whyte

* In absentia

Welsh National School of Medicine

Dr J G Lawson, lecturer in obstetrics and gynæcology University of Aberdeen, has been appointed senior lecturer in obstetrics and gynæcology

Empire Rheumatism Council

This council is appealing for £250,000 to enable it to carry out a 10 year programme of concentrated research Contributions should be sent to the Council, Tavistock House (N) London, W C 1

Royal Society of Medicine

Section of Anæsthetics—This section offers a prize (£30) for the best paper submitted by a senior registrar or registrar holding a clinical appointment in an anæsthetic department of a hospital Papers for the 1958 award must be submitted by Jan. 1, 1958 Further details may be had from the hon secretary of the section, 1, Wimpole Street, London, W 1

Sheffield Regional Hospital Board

In this board's research prize competition for 1956 prizes of £50 each have been awarded to Dr A. H. Morris, senior registrar in diagnostic radiology at Leicester Royal Infirmary, for his entry on radiological features of Hodgkin's disease in the thorax, and to Dr N M Gibbs, senior registrar in clinical pathology at Derbyshire Royal Infirmary, for his entry thrombo embolism

Society for Biological Rhythm

This society is to hold a conference from Aug 26 to 28 at Semmering, Austria, on time in biology Further particulars may be had from the secretary, A Sollberger, anatomical department, Caroline Institute, Stockholm, 60, Sweden

Laboratory Animals Bureau

Prof J H Gaddum, F R S , will open the congress which this bureau is holding at the Royal (Dick) School of Veterinary Studies, Edinburgh, on April 4 and 5 Further particulars may be had from the bureau, M R C Laboratories, Holly Hill, Hampstead, London, N W 3

National Association for Mental Health

The annual conference of this association will be held at Church House, Westminster, on April 11 and 12 The subject chosen for discussion is the maladjusted child, and the speakers will include Dr Kenneth Soddy, Dr John Bowlby, and Dr Mildred Creak Further particulars may be had from the association, 38, Queen Anne Street, W 1

Seminar for Overseas Health Workers

This seminar will be held by the Central Council for Health Education at Passfield Hall, London, from April 15 to 19 The subject for study will be the principles, methods, and media of health education Further particulars may be had from the medical director of the council, Tavistock House, Tavistock Square, London, W C 1

Royal Society

Dr D W Kennard has been appointed Stothert research fellow He will carry out research at the Physiological Laboratory, Cambridge, on the reflex activity of the spinal cord

On Thursday, Jan 31, at 11 A M , at this society, at Burlington House, Piccadilly, London, W 1, Mr A S Parkes, SC D , F R S , will open a discussion on the viability of mammalian cells and tissue after freezing Other speakers will include Dr P L Mollison and Dr Audrey Smith.

Liverpool University Medical Students' Society

The annual dinner, for past and present members of this society, will be held at the Adelphi Hotel, Liverpool, on Feb 7 Lord Cohen of Birkenhead will be in the chair and the guest of honour will be Prof Stanley Alstead, president of the Royal Faculty of Physicians and Surgeons of Glasgow Tickets (25s) may be had from the Medical Dinner Secretary, Medical School, University, Liverpool, 3

Mundesley Sanatorium

The East Anglian Regional Hospital Board is acquiring this privately owned sanatorium for use as a post acute hospital which will serve the hospitals in the Norfolk and Norwich, Cromer, King's Lynn, Yarmouth and Lowestoft, and Bury St Edmunds hospital groups (*Eastern Daily Press*, Jan 9) The transition will be gradual, but it is expected that Mundesley Hospital will be in full use in about three months

Société Française de Médecine Psychosomatique

This society, which was founded last year, would like to get in touch with other societies, groups, and individuals interested in the exchange of information on psychosomatic medicine The president of the society is Dr F Moutier and the secretary is Dr L Chertok, Centre de Médecine Psychosomatique, 54, Avenue de la Republique, Villejuif (Seine), France

Training in Hospital Administration

Applications for a further 16 training posts for hospital administrators are invited by the Minister of Health and the Secretary of State for Scotland under a scheme which began last year The posts are open to young officers of promise already employed in the National Health Service and to university graduates and professionally qualified people who wish to make hospital administration their career

The normal age limit will be 30 but candidates up to the age of 35 will be considered During their training which will normally last for three years the student administrators will be given practical experience with different hospital authorities and instruction at the Hospital Administrative Staff College of the King Edward s Hospital Fund for London or at the University of Manchester

x fees will be paid and they will also receive a salary beginning

500 applications were received last year, 143 of

ates were already in the hospital service 14

of whom already held hospital posts) and 2 women

lected

Institute of Dermatology, London

A semi permanent exhibition by Dr G Weddell on the neurohistology of the integument and changes in leprosy will be held at the institute, Lisle Street, W C 2, from Feb 5 to 2

British Hospitals Contributory Schemes Association, 1948 —This association has published its directory of contributory schemes for 1956 Copies may be had (10s post free) from the honorary secretary, Royal London Buildings, Baldwin Street, Bristol, 1

Diary of the Week

JAN 27 TO FEB 2

Monday, 28th

MANCHESTER MEDICAL SOCIETY, Medical School, University of Manchester
9 P M *General Practice* Dr J H Cyriax Manipulative Medicine

Tuesday, 29th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5 30 P M (London School of Hygiene and Tropical Medicine Keppel Street, W C 1) Prof C A Keele Causes of Pain.
ST MARY'S HOSPITAL MEDICAL SCHOOL, W 2
5 P M Mr T L T Lewis Use of Drugs in Modern Obstetrics
INSTITUTE OF DERMATOLOGY Lisle Street London W C 2
5 30 P M Mr A K Monro Gravitational Ulcers
ROYAL ARMY MEDICAL COLLEGE, Millbank London, S W 1
5 P M Sir Geoffrey Todd Operative Treatment of Pulmonary Tuberculosis and its Prognosis
ROYAL STATISTICAL SOCIETY
5 30 P M *Medical Section* (Westminster Medical School, Horseferry Road, S W 1) Mr F D K Liddell Statistical Problems of the National Coal Board Medical Service
UNIVERSITY OF LIVERPOOL
5 15 P M (Arts Theatre) Prof Wilder Penfield, O M , F R S. Cerebral Cortex of Man—an Interpretation of Responses to Electrical Stimulation (Sherrington lecture)

Wednesday, 30th

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road W 1
2 P M Dr Norman Ashton Pathology and Ætiology of Retrolental Fibroplasia
INSTITUTE OF DERMATOLOGY
5 30 P M Dr Henry Haber Nodular Lesions of the Legs
INSTITUTE OF DISEASES OF THE CHEST Brompton, London, S W 3
5 P M Dr J L Livingstone Asthma

INDIVIDUAL VARIATIONS IN EXPENDITURE OF ENERGY

J BOOYENS *
M Sc Potchefstroom

R A McCANCE
C.B.E M D, Ph D Camb F.R C P, F R S
PROFESSOR OF EXPERIMENTAL MEDICINE IN THE UNIVERSITY OF CAMBRIDGE

IT has generally been accepted that variations in individual calorie intakes are due to differences in age size, and muscular activity at work and recreation tempered to some extent by the degree of efficiency and training (Orr and Leitch 1938, Passmore and Durnin 1955, Mayer 1956a and b) It has also been shown, however, by Widdowson (1936), Widdowson and McCance (1936), and Widdowson (1947) that in any homogeneous group of adults or children, there are always some individuals who have calorie intakes greatly in excess of those of others and that the differences cannot necessarily be explained by size or obvious muscular activity. Edholm et al. (1955) took these observations a stage further when they found that cadets who appeared very similar outwardly sometimes expended surprisingly different amounts of energy in lying sitting, and standing The records for the first of these occupations were made after the cadets had been recumbent for ten minutes The men were not, therefore, in a strictly basal state, and some of the individual differences may have been due to this Similar differences were found during sitting and standing, but this is much easier to explain, for these occupations allow much more latitude, and some people are always more "restless" than others whether they sit or stand

It has been shown by Wiehl (1944) that schoolboys spend most of the twenty-four hours lying or sitting This has also been found to be true for factory workers (Bransby 1954), cadets (Widdowson et al 1954 Edholm et al 1955), and mine workers and clerks (Garry et al 1955)

In the light of these findings Edholm et al (1955) suggested that differences in the energy expended during lying and sitting might be responsible for large individual variations in calorie intake It has subsequently been felt that similar differences might underlie the facility with which some people appear to put on weight, whereas others find it difficult to do so We therefore decided on the following programme

(1) To check over the findings of Edholm et al (1955) and to demonstrate again if possible that in a group of healthy and outwardly homogeneous people, there are usually some who expend considerably less energy in lying sitting, and standing than do others

(2) To study in detail the calorie expenditure of some people who utilise large or small amounts of energy when they are lying, sitting, and standing and to find out to what extent their calorie intake and body build may be influenced by this.

(3) To single out other matters which influence individual energy requirements and if possible to find out the cause

Experimental Arrangements

General plan —A trial investigation was first made in which the expenditure of energy by healthy people was measured while they were lying, sitting and standing under comparable experimental conditions A few people whose expenditure of energy fell at the extremes of the normal range were then selected to determine and compare their total turnover of energy

Material —Fourteen females and twenty-two males volunteered for the trial investigation Information about their age, height, weight, and surface area is given in table I Apart from a few science students, all the people were attached to the Department of Experimental Medicine and were accustomed to the idea of experimental work hence psychological influences on that score were eliminated as far as possible

Standardised Procedure

All metabolic measurements were made towards the latter part of the morning or of the afternoon about four hours after the previous meal The people first lay down for thirty minutes and their pulse rate was used to indicate when their metabolism had reached a steady state (Collett and Liljestrand 1924 Karrasch and Müller 1951)

All measurements were made in the same room, in which the temperature was about 20°C A comfortable bed and an upright chair were available on which the subject lay and sat, and while measurements were being made, only the subject and the observer were in the room

In the preliminary survey the sequence of events was always the same -

During the first thirty minutes of recumbency three ten-minute samples of expired air were collected and the pulse

TABLE I—ENERGY EXPENDED IN LYING, SITTING, AND STANDING

					Expenditure of calories (per sq m per hr)

[*] Supported by financial grants from the Transvaal and Orange Free State Chamber of Mines and the South African Council for Scientific and Industrial Research

rate was measured at five-minute intervals After this thirty-minute period a fourth ten minute sample of expired air was collected The subject then sat up on the chair for five minutes, after which a ten minute sample of expired air was collected The subject next stood for five minutes, and again a ten minute sample of expired air was collected The subjects were asked to stand as they would normally stand, that is at ease

Expired air was collected with Douglas bags and a conventional mouth-piece and valve holder (Douglas and Priestley 1948) Volumes of expired air were measured with a standard calibrated dry gas meter, and samples of expired air were kept in rubber containers for analysis but never for more than an hour, to minimise the loss of carbon dioxide from the samples (Orsini and Passmore 1951)

Expired air was analysed with the automatic Hartmann and Braun (1956) analyser, and the accuracy of the analysis made with this apparatus was checked against duplicate analysis of the same samples of expired air on the Haldane apparatus (Haldane and Graham 1935) during the early stages of this investigation Differences in carbon dioxide content and oxygen deficit in samples of expired air given by the two methods never exceeded 0 09% and were mostly within a 0 05% range of agreement Calorie output was calculated from the non-protein respiratory quotient and the calorie-liberation tables of Cathcart and Cuthbertson (1931)

Six people were selected from the preliminary survey for detailed individual studies These were made as follows

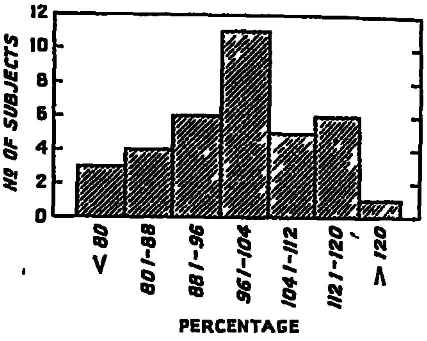
(1) All foods and liquids consumed by each person were weighed separately, and the weights were recorded daily for a week by four of the subjects and for two weeks by two of them The calorie intakes of each person for each day were calculated from the food tables of McCance and Widdowson (1946)

(2) The subjects kept an exact record of the time spent at each task or occupation on a form similar to that used by Garry et al (1955), except that the printed sheet used in this investigation covered all the twenty four hours of the day and not only eighteen of them By means of the diary sheets the times spent at the various occupations were calculated daily for each person

(3) Individual expenditures of energy at all, or nearly all, the recorded tasks were measured Douglas bags were used to collect the expired air at the lighter occupations, and the Kofranyi Michaelis portable respirometer (Kofranyi and Michaelis 1940, Orsini and Passmore 1951, Muller and Franz 1952) fitted with a standard Siebe Gorman mask during the heavier tasks The volume recordings of the Kofranyi Michaelis respirometer were calibrated by passing air through a calibrated dry gas meter into the Kofranyi Michaelis respirometer at various flow-rates At least two estimates of the energy expended at each task were made on all the subjects, and more if it was possible The energy expended on the quiet occupations—lying, sitting, and standing—was measured in each of these special subjects after fasting for fourteen hours or more and at varying intervals after meals until the post absorption metabolic level was reached Figures used in the final computation of the expenditure of energy by the six selected subjects while lying, sitting, and standing are the averages of measurements made from four to fourteen hours after the previous meal By combining the time spent (minutes) on each occupation with its cost in calories per minute the calories expended at the various occupations daily were calculated, and hence the total daily expenditures

Results

Table I gives the ages, heights, and weights of the thirty-six people Those selected for further study are shown in heavy type The figures for basal metabolic rates (B M R) shown in the table were taken to be the lowest of the measurements of oxygen consumption made in the recumbent position Usually there was little difference between the last two figures obtained, hence, for all practical purposes, the subjects were down to basal levels at the end of twenty minutes In many of the subjects there was no fall after the first ten minutes, so the gross adjustments to basal levels evidently took place during this time The frequency distribution of the basal expenditure of the men and the women is given in the accompanying figure The men's average weight for height (not given in the table) was 102 5% of the Odier and Mach (1949) standard, and the women's 101 0% The subjects were, therefore, a fair sample of a European population Their average B M R was 105 1% (females) and 101 2% (males) of the Robertson and Reid (1952) average As previously described (Kirk and Kvorning 1946), a few people even in this perfectly normal group had very low B M R Table I also gives the energy expenditure of these subjects sitting and standing and the averages for each of these activities



Distribution of basal expenditure

In confirmation of the results of Edholm et al (1955) some of the subjects differed widely from the group average when they were lying, sitting, and standing In Edholm et al 's small series one man had a relativel low metabolic rate while recumbent and a high one while standing, but most men had a consistently low or high metabolic rate at the three occupations This was true of some of the people who had high B M R in the present study (e g , subjects 4, 5, 10, 14, 22, 28, and 29), and a similar consistency was found in some of those who had low B M R (e g , subjects 7, 13, 15, 34, and R M) but others who had a normal or a low B M R had a hi metabolic rate while sitting or standing, and vice ve (e g , J B and subjects 8, 9, 12, and 24)

Among the men subject 7 and R M had exceptiona low expenditures of calories while lying, sitting, an standing, whereas subject 4 had an exceptionally high expenditure J B had a low B M R , but his sitting and standing rates were normal and high respectively, and he was selected for further study, not so much because of his exceptional expenditure of calories as because he was of very similar physique to subject 4

Of the two women selected for further study subject 34 had exceptionally low, and subject 29 exceptionally high, expenditures of calories at the three standard tasks The B M R of five of these subjects lay well outside the 10% or, at most, 15% limits usually reckoned to be "normal" (Du Bois 1927, Robertson and Reid 1952), and, if the B M R was exceptionally low or high, the expenditure of energy in sitting and standing was of the same type These variations were not consistently related to age, height, or weight/height ratio of the subjects This again confirms the findings of Edholm et al (1955) in some of their subjects (e g , numbers 5 and 6)

Table II gives the average daily intake and expenditure of calories, with their measures of variability, by each of the six persons selected for detailed study Most of the diets conformed to the conventional pattern, even to the occasional "old-fashioned" cocktail before supper but R M was eating a diet somewhat peculiar to himse in that it consisted largely of potatoes, legumes, and othe vegetables, and had no bread in it, not much meat o animal protein, and very little fat He ate nearly 1 5 kg of potatoes a day during the fortnight The diet provided 95 g of protein, 45 g of fat, and 450 g o carbohydrate daily

TABLE II—ANALYSIS OF INTAKE AND EXPENDITURE OF ENERGY BY SIX SELECTED PERSONS

Subject no	Sex	Length of study (days)	Total intake and expenditure of calories (daily average and range)		Percentage of time and energy spent on									
					Lying		Sitting		Standing		Indoor activities		Outdoor activities	
			Intake	Expenditure	Time	Cals	Time	Cals	Time	Cals	Time	Cals	Time	Cals
4	M	7	3602 (2294–4142)	3405 (2890–3897)	38 5	25	35 7	29 1	5 1	4 6	5 1	4 8	15 6	36 3
7	M	7	2417 (2144–2544)	2212 (1933–2328)	39 0	18 3	22 4	11 4			25 6	30 7	13 0	39 6
J B	M	7	3022 (2740–3289)	2900 (2751–3102)	45 7	26 2	35 5	26 4			8 9	13 9	9 8	33 5
R M	M	14	2432 (2133–3712)	2674 (2183–3183)	31 9	12 4	31 0	13 3			18 5	19 4	18 6	53 9
29	F	7	2419 (2313–2471)	2458 (2399–2593)	34 8	21 9	23 7	17 1			34 6	40 6	6 9	20 4
34	F	14	1595 (1063–1883)	1660 (1438–1952)	32 3	20 4	41 0	28 2	7 5	7 0	6 8	19 8	11 5	24 6

The subjects' work did not call for great changes in their expenditure of energy or in their intake from day to day, and there was no clear relationship between them, either immediate or delayed (Edholm et al 1955) There were, however, considerable differences between the calories expended daily by the individual subjects No 7 (male), for example, utilised only 2212 calories a day, and no 34 (female) 1660, whereas no 4 (male) required 3405 calories a day, and these average figures for expenditure were always closely matched by the intakes No 4 (male) and R M weighed themselves carefully before, during, and after their experimental periods, and their weights may be said to have remained the same throughout

The hours occupied by lying in bed or sitting down were of the now familiar order (Widdowson et al 1954, Passmore and Durnin 1955) J B spent more time than any of the others in bed, and R M less, and lying and sitting together account for from 26 7% (R M) to 54 6% (no 4) of the subjects' total expenditure of calories The time spent lying and sitting ranged from 58 5 to 81 2% of the subjects' total time No 4 and no 34 spent some time standing at outdoor lectures and ward rounds respectively, without other movements, but the others did not

Indoor activities consisted of shaving, washing and dressing, working in the laboratory, and domestic chores (table III) The outdoor activities consisted of walking, cycling, and recreational pursuits, which varied from digging holes for fence posts to cleaning a car, playing cricket, and cycling The pattern of these indoor and outdoor activities depended on the subjects' work and interests

No 4 was a male student who had no responsibilities in the house and spent much of his time sitting indoors studying Consequently his activities were mostly outside, getting to and from his work and playing cricket, but together they took up 15 6% of his time and accounted for 1226 calories a day—36% of his total expenditure

Nos 29 and 7 both worked in the laboratory but moved actively about it and sat very little Both of them also had responsibilities at home No 29 looked after her cottage and acted as gardener and carpenter It was she who dug the holes for the fence posts Consequently her indoor activities occupied 34 6% of her time and utilised about 1000 calories—40 6% of her calorie intake Her outdoor activities took up less than 7% of her time but required 500 calories—more than 20% of her total

J B's indoor activities were slight both in time and in the proportion of his calories spent on them His outdoor activities consisted of cycling about the town They did not take up much time, but they accounted for 970 of his 2900 calories

No 34 spent nearly 50% of her time sitting or standing indoors Both of these she did with very little expenditure of energy (table I) Her housework did not take much time although it used up nearly 20% of her calories Her walking and car cleaning were considerably less strenuous than J B's cycling took up little more time, and required only 400 calories a day Her total turnover of calories was therefore much lower than that of any of the others

R M's indoor activities occupied a very usual amount of time at a cost of less than those of no 29 and no 7, who expended about the same total calories He took advantage of this experiment, however, to put in as much time as possible on his usual outdoor hobbies and activities, which were cycling and walking, and in the fortnight for which he weighed his food he cycled 692 miles and on the Sunday walked 39 miles over well made roads in undulating country These activities took up 18 6% of his time and nearly 54% of his calories—about 1400 a day Apart from this exercise R M's expenditure of energy would have been little more than 1000 calories a day

Table III gives the calories utilised by the six select subjects on various tasks and occupations The energ expended at each of the recreations was only measured,

TABLE III—ENERGY EXPENDED BY SELECTED PERSONS ON VARIOUS TASKS AND OCCUPATIONS

Nature of activity	Energy expended (calories per sq m per hr)					
	Subject 4	Subject 7	J B	R M	Subject 29	Subject 34
having washing dressing &c	81	100	81	62	67	100
alking	159 (own pace)	196 (3 7 m p h) 225 (4 3 m p h)	195 (3 3 m p h) 239 (4 1 m p h)	138 (3 11 m p h) 168 (3 93 m p h)	135 (3 25 m p h) 205 (4 1 m p h)	1 1 (1 21 m p h)
ycling		171 (in town 8 6 m p h)	232 (in town 10 5 m p h)	144 (in town 8 7 m p h) 221 (in country 12 m p h)		
ousehold chores washing up making tea making beds sweeping					126	107
ving about the house standing alking occasional stairs odd obs	79			95		
rking in the laboratory (see text)		116	91		76	
creation and type (see text)	201 (cricket)				[illegible] (digging)	101 (cleaning a car)

once The energy expended on all the other occupations was measured at least twice, and any unexpected finding was confirmed several times These expenditures were measured to arrive at an over all figure for the subjects' total utilisation of calories, and some of the occupations were composite ones The figures for lying, sitting, and standing have already been shown in table I Figures for the expenditure of energy at various exercises are often given in terms of calories a minute, regardless of the person's height and weight (Edholm et al 1955, Passmore and Durnin 1955) Here, however, the results have been given as calories per square metre of body-surface per hour because the B M R is usually expressed on this basis, and this was the one used in the construction of table I They can be converted to calories a minute from the information given there

Shaving, washing, and dressing—The expenditure of calories by these subjects in these activities averaged 82 calories per square metre per hour, which is on the low side according to Passmore and Durnin (1955), and one of the figures now presented included having a cold bath and drying afterwards (R M)

Walking—The expenditures in walking ranged from 138 to 239 calories per square metre of body surface per hour according to the rate and the subject They are of the order of those given by Passmore and Durnin (1955) in their first figure, but only those for no 7 and possibly no 29 lay within the range of scatter shown by the subjects selected for their nomogram Since both the present subjects weighed considerably less than those used for the construction of Passmore and Durnin's figure they both seem to walk with more than the average expenditure of energy J B's expenditure for his given speed was considerably higher than would have been predicted from the figure R M's was lower, and those of no 34 were lower still There is evidently more individual scatter than the figures given by Passmore and Durnin suggest Moreover these workers do not mention whether women tend to expend more or less energy than do men on walking

Cycling—No 7's cycling was really a composite activity It was the journey he made four times daily between his house and the laboratory and included a little walk along a passage about one hundred yards long J B's expenditure on cycling agrees with the figure given by Edholm et al (1955) for their fifth subject, but both are on the high side for their speeds when compared with Edholm et al's other subjects J B's expenditure on cycling at 9 4 m p h would probably have agreed quite well with the figure of 7 0 calories a minute given for one of the subjects cited by Passmore and Durnin (1955) R M's expenditure on cycling was much lower than any of the comparable figures cited by Edholm et al or by Passmore and Durnin—see below

Working in the laboratory—For no 7 this meant standing, using pipettes, attending to a centrifuge, crushing ice, &c J B was emptying Douglas bags and taking pulse rates, and no 29 was standing manipulating apparatus on her bench

Other activities—No 4's cricket was net practice and consisted of bowling for a third of the time and fielding for two thirds No 29's recreation was digging holes, and no 34's [illegible]ning and polishing her car

DISCUSSION

Basal and Static Occupations

Evidently the present results confirm and extend the conclusions of Edholm et al (1955) that some people have metabolic rates for basal and relatively motionless occupations which depart much more widely from the average for the group than is usually considered to be the case In this study some people maintained these unusual rates for months on end, and they must be accepted as part of their permanent, or at any rate, semipermanent characteristics Since, moreover, adults and indeed children also spend such a large part of the twenty-four hours lying, sitting, and standing, a person with a consistently low rate at all three occupations will require less food to meet these expenditures than does one of similar build with a consistently high rate The calories expended on these occupations, therefore, are an important reason for variations in the total energy expenditure of individuals They may be the onl important cause in persons who lead outwardly simil lives and must be taken into account no less than th obvious and visible differences in active physical work

Walking and Active Exercise

These activities were only investigated in the su subjects selected for more detailed investigation, and th individual results have been compared with publishe ones rather than with the average for their own sma group Except for cadets and soldiers, walking is n a standardised exercise, and no two people use th arms and auxiliary muscles in the same way when th are on the move Nevertheless the chart given b Passmore and Durnin (1955) indicates only a minor deg of scatter at any given rate In terms of calories a minu the present subjects had a much wider one

J B, for example, walking at 3 9 m p h expended near 8 calories a minute, and R M only 4 5 This was partly d to large differences in body weight (Mahadeva et al 19 but there is more in it than that The same differences ca out in cycling R M did this exercise with very little expe diture of energy His sixteen mile run in the country was tak in three stages on a circular course involving a long hill a a rise of 100–150 feet and a descent against the wind on exposed road His expenditure on this run was lower than th of subject 7 or of J B cycling more slowly on the level is only fair to say that R M was riding a light bicycle wh had been built to his own specification, but he is both a cycl and a long distance walker of great experience and has a hig developed sense of rhythm, and all unnecessary movemen were probably eliminated from both occupations twenty fi years ago

Cause of Variations in Lying, Sitting, and Standing

If we apply these ideas about walking to the expe diture of energy while lying, sitting, and standing can see why one person may depart so widely fr the average The basal rates probably depend more the metabolism of the internal organs than do any of other rates, but there must be a muscular element them, and the small increases in the expenditure minute when people sit up and then stand up may attributed to the small additional amounts of musc energy needed for these tasks It is suggested th R M and subject 7 can achieve a high degree muscular relaxation at all three occupations keeping with this is the fact that R M's pulse ra is only 42–45 under basal conditions Subjects 4 a 29 never achieved even the average degree of relaxati and were always far above it, and J B, who had a ba rate well below the average when he was lying do and was evidently able to relax more than the avera person in that position, expended just the avera amount of energy while sitting, and his expenditu while standing, walking, and cycling were prolific Th was due to tension, minor "unnecessary" movement and lack of "rhythm"

Expenditure of Energy and Body weight

Fat men and, still more, fat women have often long for some excuse for their obesity, and physicians ha supported them in their search for some minor departu from the metabolic norm which would explain th tendency to put on weight It was thought at the out of this study that if persons were found with exceptiona low metabolic rates lying, sitting, and standing they mi all tend to be fat and have trouble in keeping their wei within normal bounds Subject 34 and J B have t trouble, but R M and subject 7 are both exceptiona thin and do not have to worry about the food they in spite of their low metabolic rates Subject 4, has a very high metabolic rate while lying, sitting, standing, is a big man and maintains his weight q easily, and subject 29 is a woman of normal proporti

These masked variations in expenditure of ene explain well enough why some people require few calo maintain their weight and others twice as many, but re is nothing to suggest that they play any part in fundamental control of appetite This is a problem ch remains to be solved, although some of the recent k on the peripheral and central mechanisms have n most illuminating (Kennedy 1951, Janowitz and llander 1955, Brobeck 1955, 1956, Mayer 1955 1956 a b) In modern life, however, the food served for the ociety" in which we live and the food eaten by nt and convention in it are adjusted unconsciously out the person who is average in all respects Persons h low expenditures of energy, whether obvious masked, can only maintain or retain a strictly average ght if they stop eating the strictly conventional ounts of food provided for their "society"

nical Relationships

The intensive search for new syndromes and for ortunities to apply new remedies has led Freedberg al (1955), Kurland et al (1955), and Tittle (1956) to cribe a condition characterised by a low basal meta ic rate with one or more of the following symptoms no other signs of myxœdema or subnormal function the thyroid gland "lethargy, easy fatigability vousness, irritability, emotional instability sensi- ty to cold, headache, ill defined skeletal pain, inished sexual potency in the male and menstrual gularity in the female" It is claimed that these sons will respond to triiodothyronine but not to roid extracts or to thyroxine If this becomes public owledge, there is a risk (*Lancet* 1956) that many o come to general practitioners with a vague story ered by these equally vague symptoms will be given odothyronine *The Lancet* goes on to say that the use triiodothyronine for this purpose is unjustifiable and uld be discouraged With this statement we agree l add that very low B M R in apparently normal and lthy persons have been well described in the past ompson and Thompson 1928, Lee 1935 Kirk and orning 1946) It has still to be proved that a B M.R -35% below the average for the group is necessarily normal Our experience and that of others (Means d Lerman 1935, Means 1937) suggest that it is not

Summary

The metabolic rates of thirty six healthy men and men were estimated while they were (1) in the basal ite, (2) sitting on a comfortable upright chair, and standing Three had rates more than 30% below, d one a rate of more than 24% above, the average for e group for all three occupations

The energy balance sheets of these four and of two other rsons were investigated for seven or fourteen days The ake was measured by weighing the food, and the output a time and motion study combined with measurements the important occupations

It was concluded that (1) the limits usually accepted the normal basal rates are too narrow, and (2) an usual rate for lying, sitting, and standing may make a eat difference to the total daily expenditure, but although a small expenditure at these three occupa- ns may lead to a small energy requirement it does not cessarily lead to obesity or even to a tendency to put weight

Our acknowledgments go to the subjects for their willing operation, and to Dr E M Widdowson for suggesting the estigation

NEONATAL COLD INJURY

DUE TO ACCIDENTAL EXPOSURE TO COLD

TREVOR P MANN
M D Lond M R C P, D C H
CONSULTANT PÆDIATRICIAN

R I K ELLIOTT
D M Oxfd
CONSULTANT PATHOLOGIST

From the Royal Alexandra Hospital for Sick Children, Brighton

EVERY winter brings in its train a number of infant deaths due to accidental exposure to cold In the past three years 14 babies thus exposed have been treated in Brighton and no less than 8 of them have died If these figures are typical of the country as a whole the yearly number of deaths from this cause may exceed a hundred

The disorder finds no place in the Registrar-General's Statistical Review, because it goes unrecognised and is hidden under various other diagnoses, of which the two commonest are hæmorrhagic pneumonia and sclerema neonatorum

When this disorder was previously described (Mann 1955) it was thought that no earlier description of it had appeared However, as Everley Jones (1953) pointed out, the account of "œdema of the newborn" given by Henoch in 1889 corresponds fairly closely to the condition that we have observed, and cold, along with bad air and wretched nourishment, was then recognised as an ætiological factor Three further accounts of the disorder, each emphasising the part played by chilling, have since been found in Dutch medical literature (Munk 1937, Campagne 1941, Veldkamp 1946), and a fourth, from Palestine, entitled Cold Injury in a Sub-tropical Climate (Nassau 1948), suggests a suitable name for the condition We make a plea for its adoption in the hope that it will encourage recognition of the disorder in this country and elsewhere

Clinical and Pathological Picture

Presenting Features

A composite picture of the disturbance may be sketched roughly as follows The baby makes satisfactory initial progress after a normal birth in the home, the pregnancy having been uneventful Although the birth-weight is often below the average full-term figure, prematurity is certainly not a constant feature

In the first week or two of life, sometimes later, increasing apathy appears, and causes concern when the infant first takes insufficient milk and shortly afterwards refuses its feeds completely As part of the general sluggishness, the cry becomes feeble and may be described as a whimper or a whine Coldness of the body to touch and swelling of the extremities or other parts, such as the eyelids, may be observed, but surprisingly both are often overlooked by the parents, and even by the attending doctor or nurse Other less constant presenting features may be related to a hæmorrhagic tendency or to impaired kidney function, thus blood may be vomited or passed per rectum, or decreasing amounts of urine may be voided until micturition ceases altogether

On detailed examination the body temperature, recorded in the rectum with a low-reading thermometer, is nearly always well below 90°F Although apparently conscious, the child lies motionless The facial expression is serene and does not suggest ill health There is an aura of coldness about the body, immediately apparent when the examining hand is placed under the clothes or cot coverings The skin, especially over peripheral parts, feels remarkably cold and corpse-like The face, hands, and feet are often strikingly red, with a particularly high colour of the eyebrows, cheeks, nose-tip, and chin At times the erythematous areas have a cyanotic tinge, often shared by the lips In contra distinction, generalised skin pallor may occasionally be found, but despite this the infant may still not appear ill Pitting œdema of at least the extremities is usual, and on careful scrutiny may be found to be more extensive than is at first apparent Local hardening of the superficial tissues over frankly œdematous parts, most usually the legs, is common at some stage of the illness and may not appear until rewarming is in progress, generally speaking this sign indicates a poor prognosis The illness is commonly complicated by some infection, characteristically rhinitis with profuse nasal discharge Although most physiological processes appear depressed by the hypothermia, the heart rate is often comparatively rapid when the patient is first seen

Clinical Course

In the majority of cases (13 out of 14) rewarming was passive, or " slow " as it is more commonly called This involves mitigating heat-loss, the baby warming up largely by its own metabolic efforts The time taken for the temperature to return to normal levels under these conditions varies widely, and we could find little or no correlation between the rate of increase in temperature and subsequent survival or death In 1 case active (" rapid ") rewarming was tried, but although the temperature was raised satisfactorily, and at first without apparent ill effect, the child died 32 hours later

The scope of investigation of recent cases is indicated in the account of case 2 (see below) The only important biochemical abnormality we have found is lowering of the blood sugar level, which may at times be profound Determinations before treatment were made in 6 cases only, in 2 the level was 10 mg per 100 ml or less, the remaining levels were 37 mg, 46 mg, 55 mg, and 94 mg per 100 ml The baby showing the highest of these levels subsequently gave values of 65 mg (second day) and 57 mg per 100 ml (fourth day)

The hæmatocrit was studied in 3 infants Although the figures tended to be high, only in case 2 were they above the normal range for the healthy newborn

The complications have chiefly been infective, ranging from rhinitis and ophthalmia, which were fairly common, to pneumonia (2 cases) and otitis media (3 cases, found at necropsy) Hæmorrhagic manifestations included petechiæ, vomiting of altered blood, *melæna*, and, perhaps in a separate category, pre-agonal bleeding from the mouth and nose

In 3 cases generalised epileptiform fits occurred which in 1 baby at least, were related to hypoglycæmia Fits are not necessarily a sign of serious import, 2 of the affected infants survived, while the 3rd died from a fulminating infection due to *Hæmophilus influenzæ*

The duration of survival of fatal cases ranged from 7 to 100 hours with a mean of about 40 hours The manner of deterioration was similar in all The baby began to look ill, erythematous areas became dusky, in several infants facial pallor was a notable terminal feature Death in all cases appeared to be due to respiratory failure In 3, terminal straining occurred during which the face flushed and shortly afterwards sanguineous frothy material poured out of the upper respiratory passages

Necropsy Findings

Necropsies were performed on all fatal cases In 5 of the 8 examined, the dominant finding was massive pulmonary hæmorrhage At first this was called " hæmorrhagic pneumonia," but the consistent absence of pathogenic bacteria on culture (and of influenza virus in the 1 case in which tissue was sent to the Virus Reference Laboratory), together with the lack of any histological evidence of inflammatory reaction in the lungs, compelled revision of this diagnosis True hæmorrhagic pneumonia was present in one case, already mentioned, which showed massive *H influenzæ* infection, but the abundant pus in bronchioles and bronchi gave a picture which even in the gross could be recognised as quite different

Hæmorrhage *in other tissues* was *not a conspicuous* feature In 2 cases there were skin petechiæ, but these were scanty and slight 3 cases showed acute gastric erosions with a small amount of bloodstained mucus in the stomach, and in 2 cases hæmorrhages were found beneath the serosal surface of the colon The findings did not suggest, in any of the cases, that the pulmonary hæmorrhage was an expression of a generalised hæmorrhagic tendency

Œdema of the extremities and deep coloration of the skin has already been mentioned A small amount of ascites (5–15 ml) was constantly present These changes, with occasional evidence of rhinitis or otitis, constituted the only other abnormal necropsy findings Clearly infection does not play a dominant rôle Massive pulmonary hæmorrhage, since it occurs in several other conditions and was not always present in our series, can hardly be regarded as pathognomonic, but if it is found *in association with mild ascites and œdema and cyanosis of the extremities, cold injury should be suspected*

Illustrative Case-records

Mild Case with Recovery

Case 1 —A baby, *aged 6 days*, birth weight 7 lb 8 oz, was admitted to the Royal Alexandra Hospital on Jan 30, 1954, with swelling of the hands and feet which had developed over the previous two days He had been born on a cold, snowy day (minimum air temperature 31°F) a few hours after his parents had moved into a new prefabricated house The only heating in the bedroom was by a small electric fire, but when bathed after birth (and daily thereafter) he was taken into the warmer front room

On examination temperature 86°F (see fig 1), heart rate 142, respirations 36 per min The face and extremities were bright pink and there was pitting œdema of the hands, legs, and feet There was no cyanosis and no hardening of the skin or subcutaneous tissues The chest was clinically clear

Treatment and progress —The child was nursed in a cot at room temperature (about 70°F) Expressed breast milk was

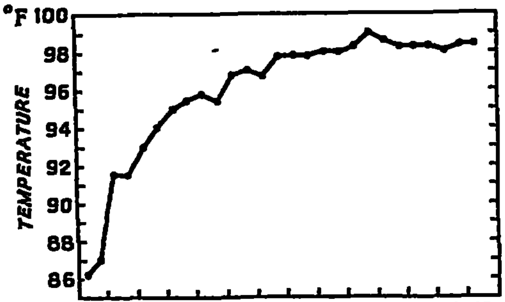

Fig 1—Body temperature in case 1

given by bottle, and aureomycin 25 mg orally every four hours for ten days The body temperature was 91°F on the day after admission and gradually rose to normal in nine days, the œdema slowly subsided over the same period No oliguria was recorded A slight eye discharge was noted on the second day in hospital but lasted less than twenty four hours After fourteen days the infant was discharged well, being fully breast fed When seen sixteen months later he was a normal, healthy child

Severe Case with Recovery

Case 2 —This baby, aged 12 hours, birth weight 6 lb 1 oz, was admitted to the Royal Alexandra Hospital on Feb 8, 1956 The birth took place in a new council house, not yet fully dried out, in a bedroom heated by one electric fire, on a cold day (minimum air temperature 34°F) Delivery, at term, was complicated by a knot in the cord and meconium stained liquor, breathing was established with some difficulty The infant was bathed in front of the fire, at 10 30 P M, and placed in a carry cot with one hot water bottle, which was not changed At 1 A M (contrary to instructions) the fire was switched off, the baby cried all night The cot-temperature on the afternoon of admission, after the fire had been on all day, was only 53°F

On examination he was a normal looking infant with an active lusty cry, there was cyanosis of the skin and a marked aura of coldness rectal temperature 81°F, heart rate 120 No œdema was present, the chest was clear Slight stickiness of one eye was noted *Investigations* (before rewarming)—Hæmatocrit 59%, hæmoglobin 16 4 g per 100 ml, blood sugar less than 10 mg per 100 ml, serum proteins 4 5 g per 100 ml, blood urea 30 mg per 100 ml, serum potassium 4 36 m eq per litre, serum chloride 96 4 m eq per litre, serum bicarbonate 27 7 m eq per litre Blood culture was sterile, and there was no albuminuria, and an electrocardiogram showed only diphasic T waves in the standard leads

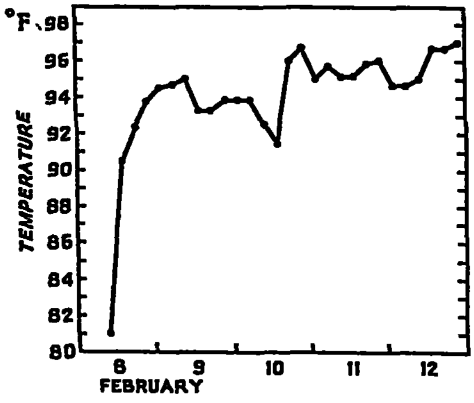

Fig 2—Body temperature in case 2.

Treatment and progress (see accompanying table)—The baby was nursed initially in an incubator, fed by compressed air at a temperature of 84°F 70 ml of fresh frozen plasma and 85 ml of 5% glucose were infused intravenously during the first twenty hours Simultaneously 15 ml of 5% glucose was given hourly by intragastric drip

Fifteen minutes after the start of rewarming, skin erythema developed over the entire body except the feet Later violent coarse limb tremors, preceded by crying, began, these continued intermittently for eight days On the third day he had three generalised convulsions and appeared moribund Both tremors and fits were probably due to hypoglycæmia The blood sugar level remained extremely low till the fourth day, when it reached a normal level following increased glucose dosage (30 g daily) The glucose intake was then relaxed to 9–12 g daily, and the hypoglycæmia promptly recurred (blood sugar under 10 mg on day 6) The temperature rose within twenty four hours to 95°F on the third day it fell transiently to 91°F, but thereafter it was never low again

On the fourth day, because of oliguria and a rising hæmatocrit (73%), a further 50 ml of fresh frozen plasma was given On the sixth day the rectal temperature reached 97°F, pulse rate 100–120, the child was bubbly at the mouth and showed generalised œdema, now congestion and pulsation of the neck and scalp veins became obvious, he vomited altered blood In view of this evidence of cardiac failure digoxin was given, with remarkably good results, the signs of failure were relieved, and there was a brisk diuresis Investigations at this stage (sixth day) showed serum-protein 4 8 g per 100 ml, blood urea 36 mg per 100 ml, serum potassium 6 05 m eq per litre, and serum chloride 94 m eq per litre

DATA ON CASE 2

—	Day								
	1	2	3	4	5	6	7	8	9
Blood sugar (mg per 100 ml)	<10	<10	<10	100		<10	73	53	60
Glucose intake (g.)	6	12	36	30	9	12	23	25	20
Lactose intake (from breast milk) (g)					4	10	15	12	24
Hæmatocrit (%)	59	75	75	73		61			57
Fluid intake (intra venous and oral) (ml)	180	350	325	280	230	240	260	430	400
Urine output (ml)	26	32	35	4	28	180 +	70 +	43 +	25 +

Recovery after the successful treatment with digoxin was uneventful, and the child was discharged home when a month old At the age of eight months he appeared quite normal

Diagnosis

The facial erythema and misleading appearance of well-being exhibited by the majority of these infants when first seen have been emphasised in both the Palestinian and the Dutch reports Nassau (1948) tellingly quotes the comment of a nurse "The child is as florid as if it had just been for a winter's walk!" Much of the delay in recognition of the fact that the child is ill is undoubtedly due to this paradoxical erythema

In 4 of our cases no one had noticed before admission to hospital that the baby had become chilled, and in none of the 14 had the severity of the hypothermia been appreciated by the midwife or the family doctor It cannot be too strongly stressed that in home confinements the baby's body-temperature should be recorded once daily at least, and that for this purpose a low-reading thermometer (range 85–110°F) should be used With the conventional thermometer it is all too easy to assume that the reading shown is the baby's temperature, when in fact it represents merely the point to which the mercury was shaken down before use

In most of the series no definite diagnosis had been reached by the doctor referring the case to hospital In some an infective process was suspected, in others hæmatemesis or melæna led to a suspicion of hæmorrhagic disease of the newborn We find that in hospital there is a strong tendency to attribute the infant's condition to an underlying infection or, if hardening of the panniculus becomes noticeable, to term the condition sclerema These two diagnoses obscure the important fact that the disturbance is primarily due to exposure to cold

It is true that a septic process in the newborn sometimes leads to slight depression of the temperature instead of the more customary rise, and doubtless when this happens the infant will be more susceptible to chilling While admitting that an infection may in this way predispose to hypothermia, we are convinced that in none of our series did sepsis play a major causal rôle

Misinterpretation of the lung changes resulting from hæmorrhage has often contributed to the assumption that the cause was infective, especially when the final diagnosis was based solely on gross necropsy findings Of course pneumonia may complicate cold injury, indeed prolonged hypothermia seems to predispose to infective complications To quote Debré and Lelong (1952) "Le refroidissement sensibilise le nourisson a l'action des germes pathogenes Ce sont des infections rhinopharyngées, otiques, pulmonaires"

There has always been great confusion over the use of the term sclerema Yet as long ago as 1811 Underwood gave a masterly clinical description of that condition Comparing his account with the syndrome described here it should be apparent that the two conditions have little in common and that their differentiation should be possible at first sight Thus Underwood, describing sclerema, correctly refers to the yellowish-white discoloration of the skin and the appearance of dying, and also remarks (which we regard as a crucial point) that "The feel of the skin and flesh is hard and resisting but not œdematous" In contrast, in cases of neonatal cold injury the skin is often erythematous, the child does not look ill initially, and, when hardening of the skin and subjacent tissue has been present, œdema has always preceded and accompanied it

Ætiology and Predisposing Factors

The majority of our infants with cold injury were first seen during spells of cold weather when minimum air-temperatures were below freezing-point It was noticeable that cases tended to be admitted to hospital immediately after a sudden fall in outside temperature Study of home circumstances, with special reference to the thermal environment to which the baby had been exposed, showed that in many instances the conditions were quite unsuitable for a confinement in winter time We have found, as Munk (1937) did, that cold injury may occur in well to-do surroundings, a comfortable and well-provided home may yet be cold

Special hazards arise when delivery occurs in very cold weather after a move to fresh accommodation, as happened in two of our cases Another source of trouble is the use of an open coal fire for heating the room where the child is born and nursed, the room-temperature may fall precipitately in the early hours of the morning when the fire goes out The same may happen with gas or electric heating if it is switched off at night as an economy measure, and this point needs special emphasis because fatal damage has occurred to infants at room-temperatures (59°F) which would be regarded as quite tolerable by adults in this country

Cold injury does not develop in every infant exposed to a low temperature, certain other factors must help to precipitate it As in adults (Pugh and Edholm 1955), the rate of cooling may be related to the thickness of the subcutaneous fat, which probably varies considerably from baby to baby, even in those of full gestational age Other predisposing factors may be asphyxia at birth (McClure and Caton 1956), birth injury, and an infection of some kind (Yllpo 1935) Chilling is of course more likely if clothing and cot coverings are lacking, and then there is the risk of unnecessary cold exposure resulting from the routine cleansing bath—a ritual practice which we find may not be waived by the midwife even in the most frigid conditions (Talbot 1925)

A further aggravating factor, to which Campagne (1941) referred, may be inanition, thus, if not operative

Treatment

The three essentials in the management of this di are to rewarm, to feed, and to prevent inf Hitherto our approach has been empirical The r mendations we make are based on the experien gained and have not been fully proved in pra nevertheless we feel that they may have some va only by marking the pitfalls we have encountere

Rewarming

The best method of treating patients subject prolonged cooling is still disputed There is g agreement that half-hearted rewarming is to be av (Burton and Edholm 1955), so the choice lies be active (rapid) rewarming (Grosse Brockhoff 19 passive (slow) rewarming (Talbott and Burton Burton and Edholm 1955) Our experience of the method has been limited to 1 case Here, althou rewarming was quite successful, the child died two hours afterwards for no very clear reason, in spect, the most probable cause was overloading intravenous fluid and there is no real justificati blaming the rewarming technique In all other slow rewarming was used either by nursing incubator with the circulating air maintained a or so above the infant's rectal temperature, or, simply, by keeping the baby normally clothed ordinary cot at a room-temperature of 70-80 method which seems to be equally effective

Feeding

One of the first effects of rewarming is accelerat the metabolic processes of the tissues, giving r increased demand for glucose Since glycogen re may already have been severely depleted durin period of exposure to cold (Grosse-Brockhoff Burton and Edholm 1955) profound hypoglycæn liable to follow, this was present in at least 2 ca our series It seems to us extremely importa recognise and correct this hypoglycæmia, but, where the pre-treatment blood sugar is normal, gl therapy is no less vital, as a considerable glycogen may still exist Administration of glucose reduce proportion of "rewarming deaths" both in dogs 1954) and man (Grosse-Brockhoff 1950)

In these infants glucose, if it is to be effective, be given in high dosage Our experience in case which the infant was profoundly hypoglycæmic for days and responded only to a glucose dosage of the of 30 g daily, seems to show that this amount was adequate, while theoretical considerations, taking account not only the infant's basal energy requiren (Smith 1951) but the needs for rewarming an replenishing the glycogen deficit, suggest that the of 30 g might even be doubled for an infant of av size The administration of so much glucose daily newborn infant is, however, a problem in itself usual 5% intravenous glucose is quite useless, if se fluid overloading is to be avoided, a more concent solution must be given Such a solution is liable to thrombosis when given intravenously, and we p therefore, to give 15-20% glucose by continuous gastric drip

Although we found no liability to electrolyte imba in the few cases where biochemical studies were u taken, it seems prudent not to continue glucose the alone for more than forty eight hours As soon a infant's temperature rises above 90°F—which, passive rewarming, it usually does within twenty hours—glucose may be given in milk, rather th aqueous solution There may indeed be no objection to the use of such a milk mixture from

The risk of fluid overloading must be guarded against The hæmatocrit may be high when the infant is first seen and may continue to rise, even reaching a level of 75% as in case 2 When this trend occurs there may be a temptation to reverse it by giving intravenous plasma, but this should be resisted The rising hæmatocrit value is the result of a fluid shift from one body compartment to another (Horvath 1951), and when, with rewarming, a contrary shift occurs, acute heart-failure may follow if plasma has been given Our experience with case 2 and other cases last winter suggests that there is a need for extreme caution in giving intravenous fluids, plasma or others, in cases of cold injury

Prevention of Infection

As infective processes are very difficult to detect in these babies, and as they seem unusually prone to septic complications, antibiotic therapy should be given from the outset Because of uncertainty of absorption of drugs from the alimentary tract in hypothermia, parenteral treatment seems advisable until rewarming is well under way Tetracycline is a useful antibiotic for prophylaxis, especially as it can be given intramuscularly or intravenously

Other Treatment

Cortisone, because of its reported value in sclerema, might seem to be indicated in cases of cold injury But, because of the susceptibility to infection, this treatment is hazardous, even with antibiotic cover, and we know of one case where an unsuspected suppurative appendicitis was found at necropsy in a hypothermic infant treated with cortisone and oxytetracycline (R W Brookfield and B W Neal, personal communication)

Hypothermia prolongs the action of certain drugs (Herrmann 1941) Because of this, barbiturates, and especially phenobarbitone, must be administered very cautiously If fits occur the possibility of hypoglycæmia must be seriously considered, and increased glucose administration, possibly coupled with subcutaneous adrenaline, may be more effective and less dangerous than anticonvulsant therapy

Both Grosse Brockhoff (1950) and Burton and Edholm (1955) concluded that oxygen administration is without value in hypothermia, and this has certainly been our impression in one or two cases where it has been used from the beginning of treatment We have considered the possibility that pulmonary hæmorrhage might have been due to over-use of oxygen, but this seems unlikely because in at least one of the cases lung hæmorrhage began before any oxygen had been given

Prevention

There can be no question that neonatal cold injury is preventable, and that, with wider recognition of the cause, its incidence will be greatly reduced Smallpeice (1955) has rightly observed that it is a reproach to us all that newly born infants should become chilled in icy bedrooms in cold weather Young infants need constant warmth by day and night No less dangerous than the coal fire going out in the early morning are lukewarm baths in cold surroundings, electric or gas fires switched off for economy's sake, or exercise of the popular British belief that some mystic quality of health resides in a stream of cold air coming through an open window

In many homes it is simply not practicable to maintain in really cold weather a steady air temperature of 65°F or more in the room in which a baby is born and nursed There are two possible solutions Firstly, the home conditions for a confinement which is expected in winter should be rigorously assessed, if the heating appliances are obviously inadequate, delivery should take place in hospital Alternatively, some form of safe portable heating equipment should be provided for use during and after the delivery

The main task, in prevention, is to ensure that those concerned in domiciliary midwifery are alert to the danger of exposing the baby to cold The simple rules for midwives set out in the appendix may help to encourage such watchfulness

Summary

Neonatal cold injury is a not uncommon disorder with a high mortality Cases generally arise after home confinements, especially in severely cold weather

Commonly the disorder is misdiagnosed as hæmorrhagic pneumonia or sclerema, the predominant rôle of exposure to cold being overlooked

Presenting features may include increasing apathy, food refusal, coldness to touch, and oliguria, but the infant does not look ill

The most constant clinical findings are hypothermia, œdema of the extremities, purulent nasal discharge, and striking skin erythema which contributes to the misleading appearance of well-being

The treatment advised is slow rewarming, liberal glucose administration by intragastric drip, and antibiotic cover

Prevention, which is of paramount importance because of the high mortality, can be achieved only by safeguarding against a fall in room-temperature This requires watchfulness by professional personnel, who should warn parents of the risk

Our thanks are due to Dr W Mestitz and Mrs Keith Powell for their kind help with the translation of German and Dutch papers, Dr Margaret Hunter and Dr Monica Barrett for their valuable clinical assistance, Sister M Janes and her staff for all their painstaking work with these babies; the many midwives in Sussex who have collaborated with us, Dr R Morrison, of the Brighton Health Department, for her guidance with preventive measures, Dr F O MacCullum for the virus investigation of one case, and Mr F Needham Green and Mr G G Morgan for providing us with details of weather

Appendix

1 In assessing for a home confinement bear in mind the season when the delivery is expected Ensure in advance that the lying in room can be properly heated, if there is any doubt about this seek medical advice

2 Make sure, in good time, that the baby is adequately provided for, especially as regards garments and cot coverings

3 The temperature of the room where the baby will be born and subsequently nursed should not be allowed to drop below 65°F in the first fourteen days of life Wall thermometers on which the 65°F low limit is clearly marked should be fixed in full view in or near the baby's cot The parents should be told how to read the thermometer and what action to take if the room temperature falls below the critical level

4 Premature infants are especially prone to chilling and may require a warm environment for some weeks At times this applies equally to newborns whose birth weights exceed $5^1/_2$ lb

5 In winter newborn babies *should not* be bathed except in thoroughly warm surroundings (70°F)

6 The baby's clothing should not restrict free bodily movement which, within loose but adequate wrappings, aids the maintenance of body warmth

7 The baby's rectal temperature should be read and recorded at least once daily for fourteen days In cases showing temperature instability readings should be continued even longer

8 Mothers should be told to feel the baby's face and extremities periodically and to report if the skin feels cold

9 If the *rectal temperature falls to 96°F or below*, medical aid should be sought In providing extra warmth in such instances, avoid increased wrappings which will insulate the baby from surrounding warmth

10 Birth injury and asphyxia (blue or white) both predispose to chilling in the newborn Babies so affected, regardless of birth weight, require careful scrutiny and may need additional warmth

11 A coal fire in the delivery room should not be used as an incinerator for damp and soiled maternity dressings after the birth

SYPHILITIC AORTIC INCOMPETENCE
WITH SPECIAL REFERENCE TO PROGNOSIS AND EFFECT OF TREATMENT

J C LEONARD *
M D Lond, M R C P
FORMERLY RESIDENT MEDICAL OFFICER

W G SMITH †
M B Aberd, M R C P E
FORMERLY REGISTRAR

NATIONAL HEART HOSPITAL, LONDON

MORE than ten years have elapsed since penicillin was first used in cardiovascular syphilis No study of its long-term results has yet been published Moreover the prognosis of the various forms of cardiovascular syphilis remains uncertain Since uncomplicated aortitis, aneurysm, and aortic incompetence have an inherently different prognosis, it is obviously necessary to consider each form of cardiovascular syphilis separately The present investigation was therefore limited to cases of aortic incompetence It was undertaken to establish the prognosis of syphilitic aortic incompetence, to estimate the influence of various factors on the prognosis, and to assess the value of the different forms of treatment, including penicillin

Many workers have held that the average survival of patients with syphilitic aortic incompetence is only 2 years from the onset of symptoms Most estimates have been based on American series containing a high proportion of Negroes, in whom the prognosis is admitted to be poorer than in white people The largest series of cases of syphilitic aortic incompetence confined to white people in the English literature are those of Cotton (1926), Grant (1933), and Grimble (1955), their findings are discussed below

Material and Methods

The present series consists of 374 patients in whom syphilitic aortic incompetence had been diagnosed at the National Heart Hospital (183 cases), the cardiac department of the London Hospital (93 cases), the department of cardiology of the Middlesex Hospital (73 cases), the Norfolk and Norwich Hospital (19 cases), and St Bartholomew's Hospital (6 cases) The study covers 30 years (1926–55) and is based on the careful examination of the very full clinical records of these patients and on personal examination of 32 of the 102 survivors

TABLE I—AGE AND SEX DISTRIBUTION

Age	20–29	30–39	40–49	50–59	60–69	70–79	80 or more	Total
Male	—	25	51	102	79	11	1	269
Female	2	13	37	32	17	4	—	105
Total	2	38	88	134	96	15	1	374

Every patient had aortic incompetence without any other valvular lesion In 360 patients (96%) either the Wassermann or the Kahn reaction was positive In the remainder necropsy findings (5), calcification and dilatation of the ascending aorta (4), a positive treponemal immobilisation test (3), and tabes dorsalis (2) provided evidence of syphilis All patients with saccular aneurysm of the aorta and general paresis were excluded 15 patients with tabes dorsalis and 1 with syphilitic meningomyelitis were retained because the outcome was unaffected by the neurological condition In addition 28 patients had minor neurological abnormalities on clinical examination, and a further 7 patients had an abnormal cerebrospinal fluid without neurological signs Other conditions present included carcinoma (3), diabetes mellitus (3), rheumatoid arthritis (3), ankylosing spondylitis (2), Reiter's syndrome (1), and pulmonary tuberculosis (1)

The age and sex of the patients are shown in table I The sex ratio was about 2 5 males to 1 female The mean age was 54 The maximal incidence was in the fifth and sixth decades in females and in the sixth and seventh decades in males All the patients were of European origin except 2 Negroes and 1 Chinese Of the 374 patients 224 were followed either to death or to the present time by examination of the hospital records or by writing to the patients or to their general practitioners Of the 150 patients who were not discovered by these means 100 were later traced from the deaths recorded in Somerset House Eventually only 50 patients (13%) remained untraced

Clinical Features

Previous History

111 patients (30%) gave a past history of either primary syphilis or gonorrhœa The mean interval from the primary infection to the diagnosis of aortic incompetence was 31 years (range 8–52 years) Information on the type and quantity of antisyphilitic treatment given in the early stages of the disease was scanty

Symptoms

49 patients (13%) were symptom-free at the time of diagnosis, this group is analysed separately later The symptoms described by the remaining 325 patients were breathlessness on exertion, 234 (72%), cardiac pain, 180 (55%), paroxysmal nocturnal dyspnœa, 71 (22%), atypical chest pain, 33 (10%), palpitation, 25 (8%), loss of weight, 18 (6%), and Adams Stokes attacks, 2 (0 7%) The mean duration of symptoms before diagnosis was 17 months

Palpitation was mentioned by 25 patients In a few instances it was due to uncontrolled auricular fibrillation, 2 patients had attacks of paroxysmal auricular tachycardia

Loss of weight was a prominent symptom in at least 18 patients (14 males, 4 females, mean age 52) and may have been overlooked in others This symptom appears to carry a bad prognosis the mean survival of the 15 patients who died was only 27 months (The mean survival of all the patients who died in the whole series was 48 months)

---

* Present address Ipswich and East Suffolk Hospital, Heath Road, Ipswich

† *Present address Sully Hospital, Penarth, Glamorgan*

Adams-Stokes attacks occurred in 2 patients with complete heart-block

Physical Signs

The characteristics of the aortic second sound and diastolic murmur are too well known to need further consideration here Attention is, however, drawn to a few of the lesser-known physical signs which may be present

Systolic murmurs—A systolic murmur was heard in 315 cases (84%), it was present in 30 of 32 patients personally examined

Thrills—42 patients (11%) had a systolic thrill at the aortic area, 21 patients (6%) had a diastolic thrill, in 11 patients both systolic and diastolic thrills were present A *systolic* thrill may result from aortic valvular stenosis, which rarely supervenes in syphilitic aortitis as a result of atherosclerotic degeneration Most workers agree that an aneurysm may cause a systolic thrill, but it is usually denied that a systolic thrill can occur in syphilitic aortic incompetence without aneurysm (Friedberg 1949, Wood 1956) Of 7 of these 42 patients examined post mortem none had aortic stenosis or aneurysm A *diastolic* thrill in aortic incompetence is commoner in syphilis than in rheumatism, it usually results from gross retroversion of the valve cusps, as in the 2 patients in this series examined at necropsy

Austin Flint murmur—A delayed diastolic murmur at the apex, with or without presystolic accentuation, was noted in 29 patients (8%) The mitral and tricuspid valves were normal in 6 of these patients at necropsy Left ventricular failure was present in 15 of the 29 patients, and in some the murmur disappeared as the failure improved Laubry and Pezzi (1926) observed that the murmur was usually heard in the presence of left ventricular failure

Arrhythmias—26 patients (7%) had auricular fibrillation at some stage of their illness, as expected, it was commoner in the older patients The mean age at the onset of auricular fibrillation was 60 Complete heart-block was present in 3 patients, in 1 of these a fibrous plaque in the region of the bundle of His was found at necropsy Paroxysmal auricular tachycardia occurred twice, and partial heart-block once

Hypertension—43 patients (12%) had a systolic pressure higher than 200 mm Hg, and 8 of these had a diastolic pressure higher than 95 mm Hg In several others moderate hypertension developed terminally in association with congestive failure

Investigations

Wassermann Reaction

As already stated, the Wassermann reaction was initially positive in 360 patients (96%) The effect of treatment on the Wassermann reaction was studied in 116 patients In 29 (25%) the test became negative after treatment, in 87 patients (75%) it remained positive It was impossible to compare the effect of different forms of treatment on the reaction

Treponemal Immobilisation Test

This test was positive in 5 patients in whom the Wassermann reaction was originally negative or became so all had received previous treatment with either penicillin or arsenic and bismuth

Erythrocyte-sedimentation Rate

The erythrocyte sedimentation rate (E S R) is raised in most untreated cases of cardiovascular syphilis (Danzer 1931 Wood 1936) Results of this investigation were available in 143 patients (38%) at some stage of the disease The standard Westergren method was used in nearly every case The mean initial reading in these 143 patients was 27 mm after 1 hour

In 73 patients the E S R was estimated before any antisyphilitic treatment had been given, the mean E S R in this group was 32 mm The effect of congestive heart-failure in retarding the E S R was less than had been expected 25 of the 73 patients had congestive heart-failure and a mean E S R of 27 mm, the mean E S R of the 48 patients without congestive heart-failure was 35 mm However, 36% of the patients with heart-failure had a normal E S R (0–10 mm), whereas only 20% of the patients without heart-failure had a normal E S R.

The effect of treatment on the E S R was studied in a small group of cases In 26 patients the E S R was estimated before and immediately after a course of penicillin, the mean reading before treatment was 33 mm and after treatment 34 mm However, a year or more after treatment with penicillin the mean E S R in 31 cases was only 13 mm These findings suggest that effective treatment lowers the E S R slowly over many months

Wood (1936) noted that 4 of his patients with a very high E S R died quickly In the present series 24 patients had an initial reading higher than 50 mm, 11 had heart-failure 15 of the 24 are dead, and their mean survival was only 14 months, compared with a mean survival of 48 months for all the patients who died in this series Of the remaining 9 patients 5 are untraced, of the 4 survivors all have received penicillin, and the E S R in 3 of them has fallen to 17 mm, 8 mm, and 8 mm, it was not estimated in the 4th patient

Radiography

Radiographs of 64 patients were personally examined Calcification of the ascending aorta was present in 22 (35%) and was confined to the ascending aorta in 7 There was calcification of the arch in 21, the descending aorta in 6, and the aortic valve in 4 The aorta was normal in 6 patients and enlarged to various degrees in 58 The left ventricle was normal in 5 and enlarged in the remainder

Either radiological reports or orthodiagrams were available for 282 patients calcification of the ascending aorta was noted in 16 of these, the aorta was specifically described as normal in 37, and the left ventricle was said to be normal in 18

If carefully sought, the true incidence of calcification of the ascending aorta in syphilitic aortitis is likely to be about 40% (Thorner and Carter 1948), in the present series this is close to the proportion found in the films personally examined It is often necessary to take oblique and postero-anterior films with highly penetrating X rays to show the calcium, which is sometimes more easily detected by fluoroscopy

Calcification probably results from atherosclerotic degeneration superimposed on syphilitic aortitis, it would therefore be expected to occur more commonly in older patients The mean age of the patients in this series with calcification of the ascending aorta was 63 Calcification of the ascending aorta is rare in atheroma alone (Jackman and Lubert 1945) and is therefore important in differential diagnosis

Electrocardiography

We examined 342 electrocardiograms, but most of the earlier tracings were confined to the standard limb leads Twelve lead electrocardiograms were available for 74 patients and these were separately analysed Table II shows the findings.

The term "left ventricular strain" has been used where definite ST depression and/or T-wave inversion has occurred in left sided precordial leads and in other leads depending on the electrical position of the heart "Left ventricular hypertrophy" describes voltage changes in the standard and unipolar limb leads and precordial leads in excess of the various criteria of

TABLE II—ELECTROCARDIOGRAPHIC FINDINGS

—	12 lead E C G	Standard leads	Total
Number of patients	74	268	342 (*100%*)
Normal E C G	6	47	53 (*15%*)
Left ventricular strain only	23	189	251 (*73%*)
Left ventricular hypertrophy only	3		
Left ventricular hypertrophy and strain	36		
Cardiac infarction and ischæmia	11	10	21 (*6%*)
Auricular fibrillation	6	20	26 (*7%*)
Left bundle branch block	4	12	16 (*5%*)
Right bundle branch block	2	10	12 (*4%*)
Complete heart block	1	2	3 (*1%*)

Goldberger (1953), Sokolow and Lyon (1949), and Gubner and Ungerleider (1943) It was impossible to differentiate left ventricular hypertrophy and strain in the standard leads only It is often very difficult to decide whether ST segment and T-wave changes are due to left ventricular strain or to myocardial ischæmia

We found only a rough correlation between the electrocardiograms and the diastolic blood-pressure, cardiac pain, and heart-failure Many of the patients for whom a twelve lead electrocardiogram is available are still alive; and it was impossible to correlate the electrocardiogram with survival

Causes of Death

222 patients died, and the cause of death was ascribed to the cardiovascular system in 207 The other causes of death were cerebral thrombosis or hæmorrhage, 4, carcinoma, 3, pulmonary tuberculosis, 1, appendicitis, 1, pancreatitis, 1, uræmia, 1, hæmatemesis from gastric ulcer, 1, coal gas poisoning, 1, barbiturate poisoning, 1, and war injuries, 1

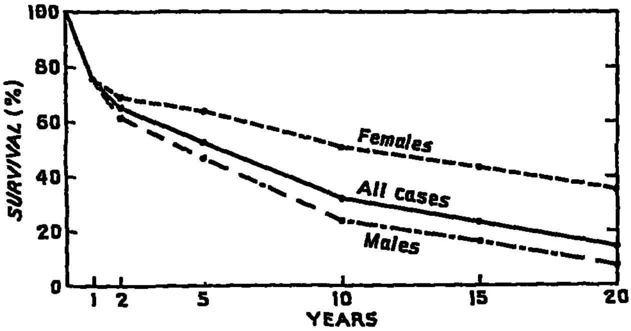

Fig 1—Survival-rate of whole series and of males and females

Of 60 patients who came to necropsy all had syphilitic aortitis Detailed information about the aortic valve was available in 36 patients, the incompetence was considered by the pathologist concerned to be due mainly to cusp damage in 31 and to stretching of the aortic ring in 5

The coronary ostia were specifically described in 35 cases the right ostium was normal in 8, narrowed in 21, and occluded in 6, the left ostium was normal in 12, narrowed in 20, and occluded in 3 Of the patients with normal ostia 3 had complained of cardiac pain, in 1 of these the left coronary artery was occluded 1 3 cm beyond the ostium by a mass of syphilitic arteritis, a rare finding in this disease, 1 other patient had moderate atheroma of the coronary arteries In 11 of the patients with ostial stenosis or occlusion there had been no history of cardiac pain

The coronary arteries were described in 19 patients, and only 4 had a moderate degree of atheroma

Bacterial endocarditis of the aortic valve was found in 1 patient, *it had been suspected clinically in 2 others* but not proved

Factors Influencing Survival

Of the 374 patients 222 are dead, 102 are alive, and 50 are untraced The survival of the whole series was determined, and an attempt was made to assess the effect of various factors on survival It is usual to calculate survival from the date of onset of symptoms Because of the difficulty in determining accurately the onset of breathlessness, we have calculated survival *from the date of diagnosis* unless otherwise stated

Merrell and Shulman (1955) have pointed out the fallacy of relying on the mean length of survival of patients who subsequently died when a considerable proportion of the original patients are alive or untraced We have therefore calculated the percentage survival according to the life-table method (see Merrell and Shulman 1955) In certain instances, however, we have also calculated the mean length of survival of patients who subsequently died, it is important to remember that these figures will be an underestimate This error will proportionately increase with larger numbers of untraced and surviving patients

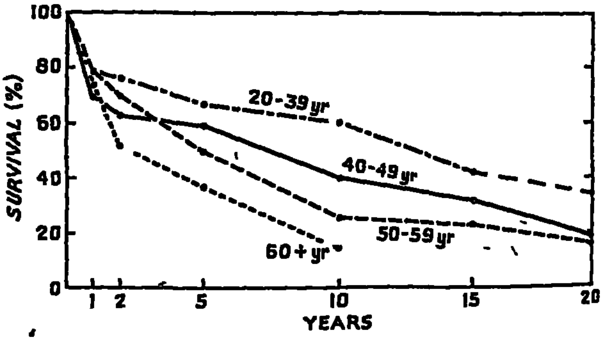

Fig 2—Survival rate of patients in different age-groups

Age and Sex

Fig 1 shows the survival-rate of the entire series *and of males and females separately* It will be noted that 75% survived 1 year, 54% survived 5 years, 32% survived 10 years, and 14% survived 20 years Females had a better prognosis than had males after the first year

The effect of age at diagnosis on survival is shown in fig 2, which shows the better prognosis of the younger patients after the second year Thus, after 10 years, 60% of those aged less than 40 are still alive, compared with only 15% of those aged more than 60 Table III shows that heart failure was much commoner in the older age groups This was probably the main cause of the poor prognosis of the older patients, but the older age-groups contained a higher proportion of males (table I) It is therefore difficult to separate the effects of age and sex on survival

TABLE III—EFFECT OF AGE, SEX, CARDIAC PAIN AND HEART FAILURE ON SURVIVAL

—	All cases	Males	Females	Age (yr)				Angina	Heart-failure
				20–39	40–49	50–59	60 or more		
Total	374	269	105	40	88	134	112	180	111
No of patients who died	222	168	54	19	57	77	69	121	89
Mean survival of patients who died (mos)	48	42	66	71	69	45	26	56	18

Table III shows the mean survival of patients who died and of the different sex and age groups These figures also show the better prognosis of the female and younger patients

Occupation

Inadequate data prevented an assessment of the effect of occupational factors on survival

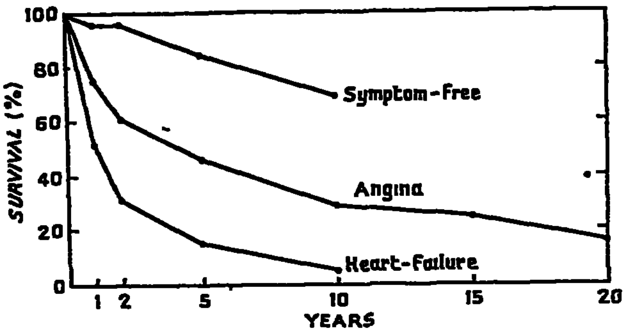

Fig 3—Survival-rate of symptom-free patients and of patients presenting with angina and with heart failure

Lack of Symptoms

49 patients (35 males, 14 females, mean age 52 years) who were free from symptoms at the time of diagnosis were analysed separately McDermott et al (1942) emphasised the good prognosis in such patients, and the present series confirms this Fig 3 shows that 96% were alive 2 years after diagnosis, 84% 5 years, and 69% 10 years Most of them had been intensively treated with penicillin and bismuth The good prognosis of aortic incompetence before the development of symptoms emphasises the importance of diagnosis and treatment at this stage of the disease

Cardiac Pain

This occurred in 180 patients, of these, 153 had angina of effort and 77 angina at rest, especially at night Table IV shows the age and sex of patients presenting with cardiac pain Angina was particularly common as a presenting symptom in women aged less than 50 The sex ratio was 2 4 males to 1 female Jones and Bedford (1943) fully described the pain of cardiovascular syphilis and concluded that the pain did not differ from that in coronary artery or in aortic-valve disease Our personal observations accord with their conclusion

TABLE IV—AGE AND SEX OF PATIENTS PRESENTING WITH CARDIAC PAIN

Sex	Age (yr)			
	20–49	50–59	60 or more	Total
Male	34 (*45%*)	54 (*53%*)	38 (*42%*)	126 (*47%*)
Female	32 (*62%*)	15 (*47%*)	7 (*33%*)	54 (*51%*)

Angina in syphilitic aortic incompetence is usually considered to carry a bad prognosis (Friedberg 1949, Levy 1951 Evans 1956, Wood 1956) Jones and Bedford (1943) found that the average survival of their patients who died with syphilitic angina was 29 months (67% of their series had aortic incompetence) In our series 180 patients presented with angina, the mean survival of 121 patients who died was 73 months from the time of onset of angina and 56 months from the time of diagnosis of aortic incompetence (range 0–324 months, see table III) 29 patients are alive, and the mean survival of this group so far is 115 months from the onset of angina and 100 months from the date of diagnosis These figures may be compared with those of Reader et al (1947), who found the mean survival of patients with cardiac pain in syphilitic aortic incompetence to be 9 4 years Fig 3 shows that 39% of patients presenting with angina lived for 10 years and 16% for 20 years Three-quarters of this small group of long survivors are women, more than half have continued to have angina throughout the course of their disease, some have had long remissions

TABLE V—AGE AND SEX OF PATIENTS PRESENTING WITH HEART FAILURE

Sex	Age (yr)			Total
	20–49	50–59	60 or more	
Male	16 ([illegible])	32 (*31%*)	39 (*43%*)	87 ([illegible])
Female	8 (*15%*)	7 (*22%*)	9 (*43%*)	24 (*23%*)

One woman presented in 1930, at the age of 34, with 5 months' history of typical angina of effort and with, more recently, nocturnal attacks On examination by Sir Thomas Lewis she had mild aortic incompetence, the Wassermann reaction was positive She was seen by us 26 years later at the age of 60, she was still having typical attacks of angina The physical signs were unchanged except that she had developed auricular fibrillation the Wassermann reaction was still positive

It is apparent from this series that the prognosis of angina in syphilitic aortic incompetence is not nearly so serious as has been previously held Long survival, particularly in women, is not rare This symptom is especially common in young women in this disease (table IV), unlike heart-failure, angina as a presenting symptom does not become more common with increasing age An average survival of 7–9 years is very like the average survival of patients with angina pectoris in ischæmic heart-disease (White et al 1943)

TABLE VI—RELATION OF DIASTOLIC BLOOD PRESSURE TO SURVIVAL

Diastolic B P (mm Hg)	0–30	35–50	55–70	75 or above
Total no of patients	28	104	144	98
No of dead patients	17	72	82	51
Mean survival of dead patients (mos)	33	40	51	59

Heart-failure

A clear history of paroxysmal nocturnal dyspnœa or definite signs of congestive heart-failure was present in 111 patients (30%) at the time of diagnosis The age and sex of these patients are shown in table V The sex ratio was 3 6 males to 1 female, a higher male preponderance than in the series as a whole Heart-failure became increasingly common in the older age groups

The grave prognosis of heart-failure is clearly shown in fig 3 52% survived 1 year, 31% survived 2 years and only 15% survived 5 years Table III shows that the mean survival of the 89 patients who died was only 18 months (range 0–100 months)

TABLE VII—TREATMENT GROUPS

Group	Males	Females	Total
1 Inadequately treated	51	11	62
2, Arsenic and or bismuth	43	20	63
3 Penicillin alone	28	14	42
4 Penicillin plus arsenic or bismuth	49	28	77

Diastolic Blood pressure

In the absence of associated hypertension or of heart failure the diastolic blood-pressure is accepted as a good guide to the severity of aortic incompetence Table VI shows the relation of the diastolic blood pressure to survival It confirms the impression that patients with the lowest diastolic pressure have the poorest prognosis

Effect of Treatment on Survival

Information on the treatment given was available in 367 patients Barnett (1933) pointed out that patients dying within a year would tend to be included in the inadequately treated group This group would thus be unfairly weighted with seriously ill patients We therefore eliminated 84 patients who died within a year of diagnosis and 39 patients who had been followed for

TABLE VIII—MEAN SURVIVAL OF PATIENTS WHO DIED

—	Group 1	Group 2
Total no of patients	62	63
No of dead patients	53	46
Mean age of dead patients (yr)	55	49
Mean survival of patients who died (mos)	63	115 (group 2a 88 group 2b 135)

less than a year, 244 patients remained for analysis These were divided into four groups according to the treatment given (table VII)

The criteria for inclusion in each group were as follows

Group 1 patients who received only potassium iodide and mercury by mouth and less than 6 injections of arsenic or bismuth

Group 2 patients who received at least 6 injections (about 3 0 g) of arsenic or 6 injections (1 2 g) of bismuth This group was later subdivided into

Group 2a a "partly treated" group who received 6–11 injections (about 3 0–5 5 g) of arsenic or 6–17 injections (1 2–3 4 g) of bismuth

Group 2b a "fully treated" group who received at least 12 injections (6 0 g) of arsenic or 18 injections (3 6 g) of bismuth or 6 *injections (3 0 g) of arsenic* plus 9 *injections* (1 8 g) of bismuth.

Group 3 patients who received at least 4 0 mega units of penicillin in 8 days (most patients had received a considerably larger dose)

Group 4 patients who received the above mentioned course of penicillin and at least 6 injections of either arsenic or bismuth

As will be seen, considerable difficulty was found in ensuring that the different groups of cases were truly comparable It was necessary to eliminate many patients, and the final size of each group is relatively small Even then it is impossible, because of the natural history *of the disease, to be certain that the results are of definite* significance

Comparison of Arsenic and Bismuth with "Inadequate Treatment"

Table VIII shows the mean survival of the patients who died in groups 1, 2a, and 2b If group 1 is compared with group 2, it appears that the survival period was nearly doubled by treatment with either arsenic or bismuth Further examination of these figures, however, revealed three important fallacies (1) 44% of group 1 were aged more than 60, compared with only 13% of group 2, (2) 34% of group 1 had heart failure at diagnosis, compared with only 16% of group 2, and (3) group 1 contained 80% males and group 2 only 67% males All these factors combined to load the "inadequately treated" group with patients having a poorer prognosis for other reasons Accordingly, all patients aged more than 60 and all patients with heart failure were eliminated The amended results are shown in table IX These selected groups, though small, were more comparable for sex and age, the balance slightly favouring the "inadequately treated" group

TABLE IX—MEAN SURVIVAL OF PATIENTS WHO DIED AGED LESS THAN 60 WITHOUT HEART FAILURE

—	Group 1	Group 2a	Group 2b
Total no of patients	27	17	28
No of dead patients	22	13	20
Sex ratio of dead patients	M 11/F 8	M 9/F 4	M 14/F6
Mean age of dead patients (yr)	48	50	49
Mean survival of patients who died (mos)	100	110	151

Similar results were obtained by calculating the survival of these selected patients from groups 1 and 2b according to the life table method (see fig 4 and table X) This method, of course, utilises the living and untraced patients as well as the dead and therefore gives a truer estimate of survival The difference in the percentage survival at 10 and 20 years is statistically significant (P approximately 0 03 and 0 005 respectively)

From the results of both methods of calculation it seems justifiable to conclude that intensive treatment with arsenic and/or bismuth substantially increased the period of survival

Comparison of Penicillin with Arsenic and Bismuth

The difficulties of assessing the effects of treatment are even greater as regards penicillin than as regards arsenic and bismuth 119 patients had been treated with penicillin 42 alone and 77 with either arsenic or bismuth Analysis of the patients who received penicillin alone (group 3) shows that, as in group 1, there was a high proportion of elderly and ill patients Thus 46% of group 3 were aged more than 60, compared with only 22% of group 4 26% of group 3 had heart failure, compared with only 10% of group 4

It therefore appears that the elderly and ill patients who, in pre-penicillin days, would have been "inadequately" treated are now given a course of penicillin alone The younger and fitter patients in this series have usually received at least one course of arsenic or of bismuth in addition to penicillin Moreover 35 patients in group 4 were symptom free at the time of diagnosis, this would favourably influence the prognosis of this group, since hardly any patients in the other groups were asymptomatic

TABLE X—EFFECT OF TREATMENT ON PERCENTAGE SURVIVAL RATES (EXCLUDING PATIENTS AGED MORE THAN 60, ASYMPTOMATIC PATIENTS, AND PATIENTS WITH HEART FAILURE)

—	Group 1	Group 2b	Group 3	Group 4
Males	19	17	10	15
Females	8	11	8	13
Total	27	28	18	28
Mean age (yr)	48	48	49	49
Percentage survival				
At 1 yr	100	100	100	100
" 2 yr	92	100	83	93
" 5 yr	76	88	83	85
" 10 yr	31	60	50	63
" 15 yr	10	52		
" 20 yr	5	35		

Another difficulty is that in groups 3 and 4 more than half the patients are still alive, it is thus impossible to calculate reliable figures for the mean survival of patients who died in these groups

We therefore calculated the survival-rates of groups 1, 2b, 3, and 4 by the life table method after eliminating asymptomatic patients, and patients aged more than 60, and patients with heart failure The results are shown in fig 4 and table X

It appears that the combination of penicillin with arsenic or with bismuth is not better than a full course of arsenic or of bismuth alone Patients treated with

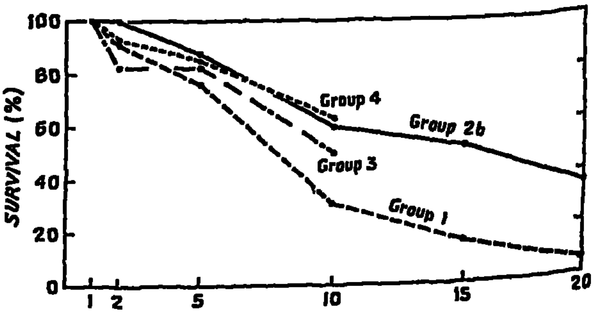

Fig 4—Effect of treatment on survival group 1, "inadequately treated", group 2b, arsenic and/or bismuth, group 3, penicillin alone group 4, penicillin plus either arsenic or bismuth

enicillin alone, however, had a rather lower survival-ate than patients in groups 2b and 4 The 'inadeuately" treated group fared worst of all.

Discussion

The previous literature on the prognosis of syphilitic heart-disease is confused and difficult to interpret Uncomplicated aortitis, aneurysm, and aortic incompetence have often been grouped together Many of the series are too small for reliable statistical assessment

One of the earliest reports in this field was that of Bruce (1911), who estimated that the mean survival of 24 patients who had died with cardiovascular syphilis was 5·3 years from the onset of symptoms Not all these patients had aortic incompetence

Cotton (1926) reported a controlled series of 114 patients with aortic incompetence, half of whom received annually a 6 week course of arsenical injections The treated and control patients "closely resembled each other in age, symptoms and signs" During 5 years observation he found a mortality rate of 24% among the treated patients and 34% among the controls

Moore and Danglade (1930) and Moore et al (1932) found a mortality rate of 90% in untreated patients with all varieties of cardiovascular syphilis during 5 years' observation; the comparable mortality among the treated patients was only 40% The mean survival of untreated patients with aortic incompetence alone was 32 months from the onset of symptoms, the mean survival of the treated patients was 65 months

Barnett (1933) criticised these results, he pointed out that the inadequately treated group was heavily weighted with patients with heart-failure and with patients dying within a year He presented a series of 99 patients which showed the fallacy of drawing conclusions from groups of patients that were not initially comparable

In reply to these criticisms Padget and Moore (1935) re-examined 165 patients previously described by Moore et al (1932) They excluded all the patients who had died within a year of diagnosis They found that, in patients who had died with aortic incompetence, intensive treatment with arsenic and heavy metals improved the prognosis only 1·37 times This figure was said to be not of certain statistical significance

Meanwhile Grant (1933) in the United Kingdom, had published his review of 1000 patients with valvular heart-disease, of whom 189 had syphilitic aortic incompetence 20 also had aortic aneurysm. He found that the average duration of life was more than 5 years, and that more than a third of the patients survived 10 years His good results have been partly attributed to the fact that his patients were ex Service pensioners leading a sheltered life He discussed the influence of treatment on prognosis and concluded that intensive treatment with arsenic reduced the mortality-rate over a 10 year period from 57 to 41%, when cases of aneurysm great cardiac enlargement, and congestive failure were excluded

Stratton's (1935) series is too small to be of much value in assessing prognosis, and his inadequately treated patients include a very high proportion with heart-failure

Cole (1937) eliminated all patients observed for less than a year and found that intensive treatment in cases of aortic incompetence increased the mean survival from 40 to 55 months

Kampmeier and Combs (1940) reported 163 patients with aortic incompetence of whom 128 were Negroes They found that 54·6% of the patients died within 3 years. After excluding patients who died within a year from the onset of symptoms they concluded that treatment with arsenic and bismuth improved the mean survival of their patients who had died from 41 to 89·5 months in white males and from 30·8 to 43·7 months in Negro males

In recent years several papers have been published on 1020 cases of aortic incompetence from the Johns Hopkins and New York Hospitals (Padget et al 1950 Densen et al 1952 Webster et al 1953) In spite of the exceptionally large number of cases no conclusions were reached on the effects of treatment on survival 119 of their patients had received penicillin but no further information was given To give their series clinical value these workers included some patients who were later proved not to have syphilitic aortic incompetence In 14% of 219 necropsies the diagnosis was proved to be wrong If, in this respect, the group that came to necropsy is representative of the entire series, a substantial element of error may have been introduced into the results However, the estimates of the effect of sex, age, angina, and heart failure on prognosis were broadly similar to ours.

Two recent American reviews have appeared in a British journal (1) Beerman (1953) summarises the difficulties in assessing prognosis, and (2) O'Brien et al (1955) present 578 cases of cardiovascular syphilis, of whom only 132 had aortic incompetence (70% were Negroes) They concluded that treatment with arsenic and bismuth had no demonstrable effect on survival, only 10 of their patients were treated with penicillin

Grimble (1955) reported 164 patients with aortic incompetence and aneurysm seen at Guy's Hospital between 1925 and 1944 In a small selected group of patients with aortic incompetence of comparable age without heart-failure adequate treatment with arsenic or with bismuth increased the mean survival from 25·5 months to 54·0 months after the onset of symptoms

From this review of previous work it is apparent that the effectiveness of arsenic and heavy-metal treatment has never been universally accepted (*Lancet* 1956) After excluding all patients dying within a year of diagnosis all patients with heart failure, and all patients aged more than 60 we have been left with two fairly comparable series of patients—"inadequately treated" (group 1) and "fully treated" (group 2b) The results indicate that, in these selected patients, the duration of life after the diagnosis of aortic incompetence has been considerably prolonged by treatment with arsenic and/or bismuth The results in the "partly treated" group (group 2a) are intermediate between those obtained in groups 1 and 2b (table IX) This is further evidence that the prolongation of life is really due to the treatment and not to some hidden bias unconsciously introduced in the selection of cases

No long-term study of the effect of penicillin on survival has yet been published. In view of the large numbers of penicillin-treated patients in the present series who are still alive our results can be provisional only Not until all the patients are dead can a firm conclusion be reached on the efficacy of penicillin With these reservations our results indicate that combined treatment with penicillin and either arsenic or bismuth is not more effective than a full course of either arsenic or bismuth alone Penicillin is, of course, much easier and safer to administer and need not be withheld from any patient, however ill. The survival-rate of patients treated with penicillin alone however, is not quite so good as that of those receiving arsenic and/or bismuth Until further and longer follow-up studies have been published, it appears unjustifiable to rely on penicillin alone. Probably it is best to give at least one full course of arsenic or bismuth to every patient in addition to penicillin

Summary

374 patients with syphilitic aortic incompetence are reported 222 patients died and 102 survive

Of the entire series 75% were alive after 1 year, 54% after 5 years 32% after 10 years, and 14% after 20 years. The mean survival of all those who died was 48 months from the date of diagnosis

Female and younger patients had a more favourable prognosis

49 patients were free from symptoms at the time of diagnosis: this group had a good prognosis, 84% being alive after 5 years

180 patients had cardiac pain at diagnosis It was commoner in females aged less than 50 and carried a relatively good prognosis 46% of the patients survived 5 years and 16% survived 20 years The mean survival of all those who died was 56 months from the date of diagnosis

111 patients had heart failure at diagnosis It was commoner in males and older patients and carried a bad

prognosis only 15% of the patients survived 5 years The mean survival of those who died was only 18 months from the date of diagnosis

The diastolic blood pressure was a good index of prognosis

In untreated patients the E S R was raised in 80% of patients without congestive heart-failure and in 64% of patients with congestive heart-failure The mean E S R before treatment was 32 mm and after penicillin 13 mm There was some evidence that an E S R above 50 mm was a bad prognostic sign

Calcification of the ascending aorta was noted in 35% of 64 radiographs personally examined It was commoner in elderly patients

After the exclusion of patients dying within a year of diagnosis, patients with heart-failure, asymptomatic patients, and patients aged more than 60 years, the mean survival of the patients who died was increased from 100 to 151 months by intensive treatment with arsenic and/or bismuth, after 10 years 60% of the "fully treated" group survived, compared with only 31% of the "inadequately treated" group This difference is statistically significant

Many of the patients treated with penicillin are still alive Conclusions in the present series must be regarded as provisional only There was no evidence that patients treated with penicillin and either arsenic or bismuth had a better prognosis than patients fully treated with either arsenic or bismuth alone Patients treated with penicillin alone, however, appeared to have a slightly poorer prognosis

It is therefore recommended that, on the information at present available, patients should receive at least one full course of either arsenic or bismuth and a full course of penicillin

We wish to thank Dr Maurice Campbell, Dr Evan Bedford, Dr Paul Wood, Dr William Evans, Dr Graham Hayward, Dr Wallace Brigden, Dr Kenneth Latter, Dr Wilfrid Oliver, and Dr James Campbell for permission to study patients under their care, Dr Bedford, Dr Wood, and Dr Evans for their valuable criticism of this paper, Dr Peter Kerley, Mr Ambrose King, and Mr J A Heady for much helpful advice, and the many general practitioners who kindly gave us information about their patients

DISCREPANCIES IN THE ERYTHROCYTE-SEDIMENTATION TEST IN RHEUMATIC FEVER

W D **Alexander**
M B Glasg

M M **Andrews**
B Sc Glasg

MEMBERS OF MEDICAL RESEARCH COUNCIL STAFF, CLINICAL CHEMOTHERAPEUTIC RESEARCH UNIT, WESTERN INFIRMARY GLASGOW

The reproducibility of the erythrocyte sedimentation (E S R) test was examined by Wintrobe and Landsberg (1935) in 9 cases (diagnosis not stated) The greatest standard deviation observed in multiple tubes containing similar oxalated blood was less than 1 mm, and Wintrobe and Landsberg concluded that E S R s may be considered to be significantly different when their difference is greater than 2 mm

For a year E S R s in this unit have been determined by two methods, each done in duplicate The degree of agreement in each pair of tubes was much less satisfactory than that noted by Wintrobe and Landsberg

The sample of blood from case 30 was lost by accident

Methods

60 consecutive patients admitted with either acute or subacute rheumatic fever were studied After an initial examination of their blood treatment was started, usually with aspirin Their blood was examined again on the fourth day of treatment, on completion of a week's treatment, and thereafter weekly

Blood was collected by venepuncture A syringe containing 1 ml of 3 8% sodium-citrate solution was filled to the 5 ml mark with blood, then the syringe was disconnected (the needle remaining in the vein), and 5 ml of blood was allowed to flow from the needle into a small siliconed container The bottom of the container was covered by a film of dried heparin (250 units) Each sample of blood was used to fill two Westergren sedimentation tubes Thus of the two methods used for sedimentation tests the first corresponded to that described by Westergren (1921), and the second was similar to the Westergren method except that the Westergren tube was filled with heparinised blood

Tubes were set up within 1 hour of collection of blood, tubes of any pair were always placed side by side in the same rack Readings were made at the end of 1 hour Correct filling of the tubes and reading of the results were personally supervised by one of us

* Cases in which the next or a later E S R test showed a similar serious discrepancy (more than 20 mm)

The remainder of the heparinised specimen was used to determine the packed cell volume (P C V) and the plasma fibrinogen level The gravimetric method of Foster and Whipple (1922), with minor modification, was used for estimating the fibrinogen level

Results

Readings at the initial examination of blood are shown in table I The first column shows the difference between the two sedimentation tubes filled with heparinised blood, the second column the difference between the two tubes filled with citrated blood, and the third column the E S R (Westergren) (mean of the two tests) The average arithmetical difference between the readings of the duplicates containing heparinised blood was 7 8 mm, and citrated blood 1 3 mm

Coincidentally with improvement in the rheumatic state and fall of the plasma fibrinogen level the discrepancies between the readings of duplicates became smaller and less numerous

A serious difference (more than 20 mm) between the readings of a pair of tubes containing similar heparinised blood was noted in 13 patients (table II) These major discrepancies were rare except during the week following admission In cases 18, 42, and 58 major discrepancies were found at two separate examinations In the remaining 10 patients though inconsistencies were noted at later examinations they did not reach 20 mm of difference

TABLE III—MULTIPLE E S R FOUND BY THREE METHODS OF TREATING BLOOD OBTAINED AT THE SAME VENEPUNCTURE

Case no	E S R (mm in 1 hr)											
	Heparinised blood				Citrated blood				Diluted heparinised blood			
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 1	Tube 2	Tube 3	Tube 4	Tube 1	Tube 2	Tube 3	Tube 4
57	46	72	48	75	64	64	64	62	74	73	73	73
59	26	61	52	73	103	103	100	102	115	115	117	110
60	35	23	29	37	43	46	46	46	44	42	42	

There was only 1 instance (case 30) of a serious difference between the readings of a pair of tubes filled with similar citrated blood (table II)

Careful inspection did not show any abnormality of sedimentation Thus, when a serious difference existed between the readings of a pair of tubes, rather large cell aggregates formed and fell rapidly in one tube, while in the other the cell aggregates were smaller and the period of aggregation more prolonged

Discussion

These results imply that E S R tests with heparinised blood are not infrequently misleading when used to follow the course of rheumatic fever

The possibility that the discrepancies found were due to some unsatisfactory feature in technique must first be considered The results were examined to see whether the first tube filled tended to show either a higher or a lower E S R from that of the second tube, but there was no such trend (table II) Tubes of any pair were set up side by side in the same rack and were therefore exposed to the same extraneous physical factors (e g temperature) A pair of tubes and their contents would be identical, provided that the specimen had been properly mixed before the tubes were filled To test this the blood was collected from each tube after the reading at 1 hour and its P C V was determined This was done on 11 occasions when there was a serious difference between the readings of a pair of tubes, and proved that mixing had been satisfactory in all 11 cases

When 10 mg of oxalate per 5 ml of blood was used as anticoagulant, Wintrobe and Landsberg (1935) found that the E S R did not differ significantly from that of heparinised blood It therefore seemed likely that if heparinised blood showed inconsistent sedimentation oxalated blood would do so too In 2 cases in which a

TABLE IV—E S R IN BLOOD OF PATIENT AGED 24 WITH GONOCOCCAL ARTHRITIS

December	E S R (mm in 1 hr)							
	Heparinised blood				Citrated blood			
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 1	Tube 2	Tube 3	Tube 4
17	70	61	76	110				
21	115	117	100	95				
28	93	78	57	97				
29	53	107	97		[illegible]	51	52	
30	50 40*	45 77*	[illegible] 38*	77 35*	[illegible]	[illegible]	[illegible]	54

Heparin 50 units per 5 ml of blood was used except for values marked * where 1 0 units per 5 ml blood was used On each occasion tubes 1 2 3 and 4 in that order were filled from the same sample of blood and placed in the same rack serious discrepancy was noted between the readings of sedimentation tubes containing heparinised blood another 5 ml of blood was obtained and collected in the oxalate mixture of Heller and Paul (1934) From each oxalated specimen four Westergren tubes were filled, the readings at 1 hour were 34, 17, 35, and 55 mm, and 58, 114, 108, and 61 mm

The column of blood in the Wintrobe tube is identical with that in the Westergren tube except that it is half the length (100 mm instead of 200 mm) In the shorter (Wintrobe) tube maximal sedimentation (due to packing) occurs more rapidly, and discrepancies at 1 hour would probably be less common than in Westergren tubes Therefore the frequency with which the classical Wintrobe method would show a lack of reproducibility cannot be inferred from the present results

The question whether the more reproducible results obtained with citrated blood were due to the effect of dilution or to the citrate ion was investigated, and it was concluded that dilution was the important factor In 3 cases multiple sedimentation tubes were filled with heparinised blood, citrated blood, and heparinised blood diluted with physiological saline solution (1 ml of saline solution to 4 ml of blood), all the blood having been obtained at the same venepuncture The results appear in table III

Of the present 60 patients with rheumatic fever 14 had a grossly inconsistent E S R at some stage of their illness This was found by setting up duplicate tubes, so the true incidence is almost certainly higher For example, in 1 case four tubes containing blood from the same sample showed readings (as mentioned above) of 34, 17, 35, and 55 mm Since six different pairs of these four tubes can be set up and only one pair agree, the chance of agreement is 1 in 6 (17%) Additional tubes from the same sample of blood might change that chance

Results obtained in a patient with gonococcal arthritis (table IV) indicate that inconsistency in the E S R is not confined to patients with rheumatic fever

Summary

In following the course of rheumatic fever E S R tests made with either heparinised or oxalated blood may be seriously misleading, results being obtained which are not reproducible

Repeated E S R tests were made both with citrated and with heparinised blood in 60 patients with rheumatic fever

In 13 patients (22%) there was at some stage in the disease a serious difference (more than 20 mm) between the readings of duplicate Westergren sedimentation tubes filled from the same heparinised sample of blood

Discrepancies persisted when oxalated blood was used instead of heparinised blood

In the shorter Wintrobe tube discrepancies would probably be less common (owing to earlier packing) than in the longer Westergren tube, therefore the frequency with which the classical Wintrobe method shows discrepancies cannot be inferred from the present results

In case 30 there was on one occasion a serious difference between the readings of a pair of tubes filled with citrated blood The more reproducible sedimentation of citrated blood seems to depend on dilution and not on the presence of citrate ions

Serious discrepancies between the readings of duplicate E S R tests are not confined to patients with rheumatic fever, they were found in a patient with gonococcal arthritis

PAIN is a subject of absorbing interest, but many patients with chronic pain are difficult people to assess, and the neurologist may feel justified in introducing some guile into his programme of cure Pain thresholds can be influenced by so many factors that he should at times be prepared to embark on what might be termed a game of bluff with his patients' higher cerebral mechanisms Thus he should not despise building up a certain atmosphere of the miraculous around his pain clinic, for this introduces a desirable physiological influence at a most important level

Among the more difficult varieties of chronic pain is post-herpetic neuralgia, which develops in about one case in ten of herpes zoster This complication cannot be correlated with the severity of the illness, but is much more likely in the elderly—the patients usually being over the age of 60, and often over 70

The pain seems to be a continuation of the discomfort felt before the rash appeared, and the patients may become demoralised by it It is arguable that all such patients have a low pain threshold, and for their excessive suffering we may, if we so wish, blame their parents, who during their early years failed to establish a healthy indifference to minor traumata and other painful states! However, these patients cannot be treated successfully by psycho-analysis

What we loosely term the psychogenic factor is a physiological process which is interfered with by frontal lobectomy Beecher (1956) calls it "the processing" of the pain mechanism It is a personal matter, and, as it is liable to take charge of the clinical picture if the pain continues for long, we should make a plea for intensive treatment, preferably with admission to hospital, within a very few weeks of the pain developing The elderly patient who has had severe pain for 5 or 10 years is not *easy to deal with*

Post-herpetic neuralgia resembles causalgia, which is associated, for example, with a partial lesion of a sensory nerve All who have experience of nerve injuries know the importance of full activity of the affected part if causalgia is to be avoided, and, in the same way, causalgia after herpes zoster is commoner in those who sit at home, doing little but nursing and protecting the sensitive area This is a common but fundamental mistake in dealing with any such pain, and we find that as soon as the rash is healed the affected tissues should be moved freely, and the scarred area rubbed General exercises help It is probable that the higher prevalence of pain in the elderly is correlated more with their inactivity than with their age We have all visited these sufferers in their homes, where, in a stuffy room, the patient sits crouching beside a fire, brooding over her pain And we shall do well in these circumstances to remove her from the unhealthy environment to the matter of fact atmosphere of a hospital ward For, although successful treatment usually depends more on physical than on psychological procedures, success breeds success in the treatment of chronic pain, and our results now seem to be so good, that the patient, soon after admission, comes to feel that it is just a matter of time before the nerves responsible are brought under control Among the many whose pain has a genuine physical basis, there are a few hysterics who are determined to make as much fuss as possible, and for them the concentrated treatment introduces a valuable element of discipline their symptom, which was once a protection, becomes a liability, so they cast it aside

---

* Based on a communication to the Association of British Neurologists, Nov 16, 1956

Material and Methods

The present study concerns a hundred cases of post-herpetic neuralgia seen during the past 10 years or so—fifty referred to our neurosurgical colleagues and fifty referred to our neurological unit The average age in both groups was 66 years, and 60% were women In thirty-two of the surgical group, the trigeminal nerve area was affected, but in our group the number was twenty-three

The surgical group was somewhat negative from the therapeutic point of view, because surgery or alcohol nerve block was generally (and very wisely) avoided, but in recent years most of the medical patients have been admitted to hospital and submitted to concentrated treatment of one kind or another, with results which are so encouraging that we have come to look forward to admitting patients with post-herpetic neuralgia Certainly, our results are improving with experience

As has already been mentioned, the type of pain in these cases is one which is associated with a partial lesion of a peripheral nerve, and has features similar to those observed in causalgia There is a raised threshold to some forms of sensation, and, indeed, there may be complete anæsthesia of the scarred area (especially when the first division of the trigeminal nerve is involved) Often, however, there is also some hyperæsthesia in the scarred area, or at the edge which is overlapped by adjacent nerves (Weddell et al 1948) It has become evident that when hyperæsthesia is a prominent feature, the chances of cure are specially good

It is quite easy to remove the hyperæsthesia temporarily by blocking nerves or infiltrating the skin with procaine, and it is important to study, without delay, the effect of this procedure on the spontaneous pain In many instances this simple procedure gives remarkable relief for several hours, and frequent repetition of the procaine block often leads to increasing periods of freedom until relief may be permanent and the affected area no longer hyperæsthetic Procaine block of the nerves supplying the skin adjacent to the scarred area may be specially important Thus in ophthalmic herpes, block of the occipital nerves on the side involved may be beneficial, as well as the supratrochlear and supraorbital nerves on the opposite side

Hyperæsthesia can be abolished also by a mechanical vibrator It still does not seem to be widely known that a vibrator with a vulcanite applicator, held lightly on a hyperæsthetic area *for 5–10 minutes, acts* as a local anæsthetic, without the trauma of a needle, and removes cutaneous hyperæsthesia It does the same with a tender scar We used these appliances first for percussing neuromata in amputation stumps (Russell and Spalding 1950), and we now use them freely in the hospital ward, and when necessary lend them to the patients to take home Resting the sensitive area on a hard surface for half an hour has, by the action of direct pressure a similar effect in removing hyperæsthesia, and is especially useful where the trunk dermatomes are affected

Thus if there are areas of hyperæsthesia, remarkable benefit is derived from the removal of this sensitivity Presumably the nerve fibres concerned with firing hyperpathic sensations are very easily traumatised into inactivity by a vibrator

Vibrator ('Pifco massager') being applied by the patient (case 4) to the suboccipital region, for its local anæsthetic effect

This effect, although only temporary at first, on repetition soon becomes longer-lasting and eventually permanent The relief often provided by the removal of hyperæsthesia shows that, whatever the lesion is in the posterior-root ganglia, this is not where the distressing afferent impulses originate It is natural that, as the pain is relieved, the patient's confidence in the result of the treatment rises, and this improves matters still further Whichever method is used, repeated treatments are followed by disappearance of the hyperæsthesia, and this commonly leads to striking relief of spontaneous pain

This removal of all hyperæsthesia from the scarred and the adjacent areas may be the only treatment required, but sometimes pain persists and further steps are necessary

One of the most useful of these is to observe the effect of interspinous hypertonic saline, 0·4 ml of 6% saline being injected near the segment affected (Kellgren 1939) This may aggravate the pain temporarily, but may then be followed by relief for several hours When the face is involved, suboccipital injection is often surprisingly appropriate The ligamentous tissue into which these hypertonic saline injections are given lies only a short distance under the skin—deep injections are not given, and indeed might be dangerous

The ophthalmic cases may be difficult, and it may be helpful to shave the hair well clear of the anæsthetic zone, to give access to the adjacent areas Unlike the patient with *tic douloureux*, who will submit to anything, these patients may refuse to have their hair cut—"it's not so bad as all that"

Other methods, such as locally applied galvanism, procaine ionisation, sympathetic nerve block, and skeletal traction, may all be useful in certain circumstances In general, it is desirable to follow one treatment quickly with another, especially in the more difficult cases Some positive local action of a physical type, several times daily, may be desirable

We have no experience of extensive skin flap reflection, as advocated by Abbott and Martin (1951) and others, but this should be very successful if the flap includes a strip outside the scarred area, supplied by adjacent nerves In our opinion, X-ray therapy and alcohol nerve block should not be used in the treatment of herpes zoster at any stage X irradiation often makes matters worse in the chronic stage, and seems undesirable in the acute stage, because it helps neurotropic viruses to invade the nervous system Nerve-root section and alcohol nerve block also do not seem to us to be desirable for these cases Operations on the pain-tracts of the spinal cord are unlikely to give relief, while frontal lobe operations are an indication of defeat which we have so far avoided

Results

Patients seen within a few weeks of the acute stage are naturally the easiest to deal with, but even those who have suffered for many years respond to a determined attack " from all sides "

It is clear from follow-up studies that the great majority of the patients treated in recent years have been considerably relieved, and in some a spectacular cure has been achieved However, the methods used have been improving steadily and it seems more helpful to describe the treatment given to the last few patients treated They have not yet been followed for long, but with good early results there is generally some lasting relief

The following are the last five cases whose treatment has been completed

Case-reports

Case 1—A woman aged 64 developed ophthalmic herpes on the right side on Oct 23, 1955, and was admitted for 10 days to the Oxford Eye Hospital, where aureomycin was given After this illness, she complained of severe right frontal pain, and became irritable, depressed, and sleepless For this, many drugs, including pethidine, were prescribed, but no local treatment was given 2 months later, there was severe hyperæsthesia in the scarred area, which she had not dared to touch or wash on this account There was scarring in the right frontal region, along with keratitis and periorbital œdema In the scarred area, there was a mixture of sensory loss and marked hyperpathia She was depressed and miserable

The patient was admitted to Stoke Mandeville on Jan 6, 1956, and a vigorous policy was adopted of shampooing the scarred area and repeated massage with olive oil along with local treatment for the ocular inflammation The frontal area was massaged for 10–15 minutes three or four times daily There was considerable osteo arthritis of the cervical spine, and periods of neck traction (6 lb) while she was lying in bed added considerably to her comfort These simple measures were followed by remarkable relief and improvement in morale She was discharged on Jan 25, and 6 months later her condition was reported to have improved steadily since she left hospital

Case 2—A man aged 46 developed herpes zoster in the right occipital region in August, 1955 After this, there was persistent pain in the affected area with frequent sharp spasms of severe neuralgia He was admitted to Stoke Mandeville Hospital on Jan 20, 1956, and the only abnormality was marked tenderness over the scarred area Vigorous local massage was begun without delay On one occasion, 0 3 ml of 6% saline was injected into the interspinous ligament between the spines of the 2nd and 3rd cervical vertebræ, the pain was reproduced in the scarred area for 5 minutes, but then disappeared for several hours Treatment was then continued with a mechanical vibrator and massage to the sensitive area, each being applied three times a day for 10–15 minutes When he was discharged on Feb 2, the pain had all but disappeared, but he was supplied with a vibrator to use at home Seen on Oct 20 he had remained comfortable, except for some short periods of pain lasting 5–10 minutes once a day It was not considered necessary to readmit him

Case 3—A man aged 71 developed ophthalmic herpes zoster on the left side in November, 1952 Since then, he had had continuous pain in the left half of his scalp as though a nail were being driven through my head " Treatment with chlorpromazine and injections of vitamin B_1 (aneurine hydrochloride) and B_{12} (cyanocobalamin) had failed to give relief When he was admitted to Stoke Mandeville Hospital on June 20 1956, there was considerable scarring and some anæsthesia of the scalp in the left frontal region with a very tender area over the left eyebrow the frontal pain was also aggravated by pressure on the upper alveolar margin where two teeth had been extracted 2 years previously

Procaine block of the left supra orbital auriculotemporal and greater occipital nerves abolished the pain for the first time since its onset the sensitivity of the alveolar margin also disappeared He was then encouraged to apply a mechanical vibrator to the sensitive areas for 10 minutes every 2 hours while he was in hospital until his discharge on July 2 During this time he had *no* return of pain, but *it* returned 2 weeks after discharge—he had stopped treatment owing to pressure of work, but he was not prepared to come into hospital again until he had more spare time It is obviously desirable that a further period of intensive local treatment should be given

Case 4—A man aged 60 when first seen in July, 1950, had had severe ophthalmic herpes zoster a year previously Since then there had been a severe pain in the left frontal region, which was heavily scarred He had a hyperæsthetic zone over the upper edge of the scarred area, and tapping here caused a shooting pain above the left eyebrow He was first advised to press firmly with the wooden handle of a clothes brush over the sensitive zone for 10 minutes three times daily, and this gave considerable relief He also found that resting the sensitive frontal region on a table for 10 minutes had a relieving effect, and during the succeeding 5 years there was a steady tendency to improvement, provided he continued to apply local pressure as a numbing agent

He was, however, admitted to Stoke Mandeville Hospital on Sept 29, 1956, to see whether more could be done, for some pain had now spread to the suboccipital region on the left side This discomfort was relieved by injecting procaine into the left suboccipital muscles, and the long standing discomfort was abolished for 8 hours by blocking the supra orbital, supratrochlear and auriculotemporal nerves These injections were repeated two or three times, and the temporary relief was prolonged by using a mechanical vibrator which was provided for him to take home

Case 5—A woman aged 80 developed herpes zoster in the left mid thoracic zone in June, 1955, and complained of persistent severe pain in the scarred area There was also marked hyperæsthesia

She was admitted to Stoke Mandeville Hospital on Oct 27, 1956, and daily procaine blocks to the sensitive intercostal areas were given for 3 days Local massage was given frequently, and procaine by ionisation was applied twice daily for a week over the whole sensitive area After some further procaine nerve blocks, the hyperpathia almost disappeared and could be further relieved by vigorous massage which she was encouraged to apply herself several times a day

Discussion

These case records indicate that the first thing to do is to institute vigorous local treatment of one kind or another, and to combine this with local anæsthetic procedures, of which the mechanical vibrator is the most useful, for it can be applied by the patient himself as often as required

Some of our methods are probably having some effect by providing competing stimuli to the thalamus as well as by actually blocking afferent discharges However, in these cases it is important to use every trick of thalamic distraction one can think of Thus a competing stimulus may well explain the effect of counter irritation, or the remarkable relief, in some cases of causalgia, when cold is applied The electrical treatment of neuralgia, so much used 50 years ago, may have a similar basis In any case, it is clear that this wide approach to the problem of pain, however " organic " it may be, is well worth while

The methods described here are clearly applicable to many other forms of intractable pain, as has already been reported by Fischer Williams (1956)

Summary

A hundred cases of post herpetic neuralgia are considered, and the problems of treatment discussed

Post herpetic neuralgia can usually be relieved by concentrated treatment to reduce pain thresholds in the tissues adjacent to the scarred area

The removal of hyperæsthetic zones is important, and for this the repeated use of procaine nerve-block and of a mechanical vibrator, are specially valuable

The methods used in treating five recent cases are described

We are indebted to Mr J P Pennybacker for permission to refer to patients under his care

A DIET RESTRICTED IN REFINED CEREALS AND SATURATED FATS:

ITS EFFECT ON THE SERUM-LIPID LEVEL OF ATHEROSCLEROTIC PATIENTS

E VAN HANDEL* Ph D   H NEUMANN Ph D

TH BLOEM M D

From the St Antoniushove Hospital, Voorburg, Holland

IN parts of the world where atherosclerosis is common the quality and quantity of the diet of the majority of the population differ significantly from those in countries where the disease is rare Atheroma may possibly be caused by a high intake of cholesterol, fat, calories, saturated fats (with relative deficiency of essential fatty acids), and degerminated carbohydrates (with deficiencies of vitamins and minerals) (Van Handel 1955)

Lowering of serum-cholesterol by a diet low in lipids has been reported by Keys (1952) Morrison (1955), similarly, used for atherosclerotic patients a low lipid diet supplemented with wheat germ Groen et al (1952) reported a fall in serum cholesterol in normal volunteers on vegetable diets, while Kinsell et al (1953) and Beveridge et al (1955) found that the serum-cholesterol was lowered by a high intake of certain oils which are rich in essential fatty acids The work of Bronte Stewart et al (1956) confirms that in short-term feeding experiments the serum cholesterol level is related to the source of the fat consumed An interesting new finding was the cholesterol depressing action of highly unsaturated marine oils

In the past 3 years we have routinely treated atherosclerotic patients with low-fat diets—i e, diets in which less than 20% of the total calories is derived from fat These diets reduced serum lipids in some cases but were without effect in others, or occasionally even raised the serum cholesterol Furthermore, the majority of patients became mentally depressed and physically weak during severe fat restriction (unpublished observations)

Therefore it was decided to abandon the low fat diet, but to restrict added fat to unsaturated soybean oil Legumes were added to provide a rich source of magnesium manganese, copper, and B vitamins including choline Peanuts and soybean flour provide additional unsaturated fats. Soybean products play an important rôle in the diet of most Oriental peoples A detailed discussion of the composition and the possible value of these food items in the prevention of atherosclerosis was published earlier (Van Handel 1955). The present study reports the effect of this new regimen on the serum cholesterol and phospholipid levels

TABLE I—PATIENTS WITH INITIAL SERUM CHOLESTEROL BELOW 250 MG PER 100 ML

	Serum-cholesterol (mg per 100 ml)			Serum phospholipids (mg per 100 ml)		
	Highest	Lowest	Average	Highest	Lowest	Average
Initial	240	160	215	280	175	240
Final	270	152	215	290	180	240

Methods

Estimations

Serum was extracted with Bloor's mixture Cholesterol was determined by the method of Fidler (1934) and lipid phosphorus by dry ashing with magnesium oxide (Van Handel 1954) Phosphorus was estimated by the method of Fiske and Subbarow (1925)

The Diet

Not allowed.—Lard and other animal fats, shortening, white bread, and foods made from degerminated flour and cereals

Restricted—Margarine and butter to 25 g a day

Allowed ad lib—Whole-wheat bread, liquid soybean oil as cooking fat, lean meat, milk, cheese, and eggs

Obligatory daily supplement—2–3 g of soy lecithin (the approximate amount which is lost in the degumming of 100 g of soybean oil), 25–50 g peanuts 25–50 g peas or beans, and 25–50 g 'Nurupan' (whole soybean flour)

Thirty-four patients followed the diet for periods ranging from 30 to 360 days Ten of them had been treated with a low-fat diet for from 3 months to several years before changing to this regimen All had previously shown clinical signs of coronary insufficiency, with or without myocardial infarction About half the patients were admitted to hospital for a period of 4 to 12 weeks Observations could then be made while they were under strict dietary control Of course, it is much more difficult to maintain control in outpatients, but a number of patients who did not follow the diet consistently have been excluded from this report

Results

In a group of sixteen patients with initial serum cholesterol levels under 250 mg per 100 ml, the diet had no significant effect (table I) The change of serum cholesterol was 0–10% They took the diet for 30–300 days (average 160)

TABLE II—PATIENTS WITH INITIAL SERUM CHOLESTEROL ABOVE 235 MG PER 100 ML

	Serum-cholesterol (mg per 100 ml)			Serum phospholipids (mg per 100 ml)		
	Highest	Lowest	Average	Highest	Lowest	Average
Initial	400	235	300	380	220	290
Final	250	172	228	282	180	250

Six of these sixteen had been taking a low fat diet for 90–300 days before they were transferred to the experimental diet This change did not cause a rise of serum lipids

Fourteen patients with initial levels of cholesterol over 235 mg per 100 ml showed a steady decrease in serum-cholesterol (table II) They took the diet for 30–330 days (average 110) Four of these fourteen had previously been treated with a low-fat diet and had maintained their high serum cholesterol during this period

Some typical data in a few patients, who responded well to the diet, are presented in detail in table III

Discussion

The present study was undertaken to evaluate the effect of a regimen low in saturated fatty acids and degerminated carbohydrates on patients with clinical

atherosclerosis. The patients did not object to the substitution of soybean oil for solid fats. In most cases the whole family changed over to soybean oil as the source of cooking fat. Soybean flour was incorporated in several dishes such as soup, biscuits, and breakfast cereal, but some patients preferred to take it in a glass of milk or water. Not only those who were previously kept on diets very low in fat, but also the patients who had not previously followed a special diet, showed noteworthy improvement of disposition and of the ability to perform normal activities. Though no patient died, it would be premature to draw clinical conclusions, for we had no controls.

A steady drop of serum cholesterol was achieved and maintained during the many months of observation, but only when the initial values were high. A considerable number of our clearly atherosclerotic patients, on free diets, had serum cholesterols between 160 and 250 mg. per 100 ml. The blood lipids of these did not change significantly on the experimental diet.

The value attached to cholesterol-depressing diets is closely connected with the common belief that the lipids in atheromatous deposits derive from the plasma, but there is no strong experimental evidence for this assumption. The alleged atherogenic effects of fats in general, and of highly saturated fats (without cholesterol supplements) in particular, have not been confirmed by clear-cut experiments. In Java, where the highly saturated coconut oil is the main source of cooking fat, the incidence of clinical atherosclerosis is very low (deLangen 1935). To investigate whether saturated fats play a rôle in atherogenesis, data from such countries as France and Argentina, where the consumption of meat and dairy products is large and where unsaturated oils are used for cooking, should be compared with similar data from (non-Western) areas where coconut oil is the main source of cooking fat.

It is unlikely that a diet which merely substitutes unsaturated for saturated fats can prevent atherosclerosis; therefore our tentative diet includes other factors in addition to essential fatty acids.

Our results are compatible with the hypothesis that high blood lipids in atherosclerosis are caused or maintained by deficiencies in Western staple food.

Summary

A diet restricting animal fats and degerminated flour and with supplements of soy lecithin, soybean oil and flour, peanuts, and peas or beans, was successful in lowering the serum lipids in atherosclerotic patients where they had previously been high.

This investigation was supported by a grant from the Dutch Dairy Board (Bedrijfschap voor de Zuivel). The 'Nurupan' was supplied by G. Dogens Ltd., Rotterdam, and made by Karl Wildermuth, G.M.b.H., Dusseldorf, West Germany.

HYPERNATRÆMIA AND HYPERCHLORÆMIA IN BULBAR POLIOMYELITIS

E. N. ALLOTT
D.M., B.Sc. Oxfd, F.R.C.P., F.R.I.C.
GROUP PATHOLOGIST, LEWISHAM GROUP LABORATORY, LEWISHAM HOSPITAL, LONDON

THE association of high serum sodium and serum chlorine levels with scanty urinary excretion of sodium and chlorine is rare. The commonest cause is severe dehydration, as in some cases of diabetic coma and in enteritis of infants; in most of these the condition is only temporary, and excretion of sodium and chlorine begins again as soon as the dehydration is overcome.

In 1939 I observed 5 cases of hyperchloræmia and hypernatræmia associated with minimal urinary excretion of sodium and chlorine in patients with intracranial lesions of various types (Allott 1939). Since then hyperelectrolytæmia has been described in association with various forms of intracranial lesions: after the removal of a craniopharyngioma (Peters 1948), in various lesions of the frontal lobes (Sweet et al. 1948), in a case of bilateral occlusion of the anterior cerebral arteries, a case of craniotomy for chromophobe adenoma, and a case of hemiplegia (McCarty and Cooper 1951), in cases of severe head injury (Higgins et al. 1951, 1954), in encephalopathy following sulphonamide therapy (Luetscher and Blackman 1943, Goodale and Kinney 1949), in a case of total pituitary hypofunction (Engstrom and Liebman 1953), and in cases of cerebral disease most of which were described as "encephalomalacia" (Schoolman et al. 1955). In many of the published cases observations were very limited, being confined in some of them merely to a single observation or to raised serum electrolyte levels with no reference to urinary excretion.

I have recently had the opportunity, through the courtesy of Dr. J. P. Marsden, under whom the patients were admitted at Joyce Green Hospital, Dartford, of studying in detail two cases of poliomyelitis with cerebral involvement, one of which showed the full picture of hyperelectrolytæmia with suppression of the urinary excretion of sodium and chlorine, the other showing changes which may represent the early stages of this condition.

Both patients presented with severe bulbar poliomyelitis requiring artificial respiration with an intermittent positive pressure machine; both initially passed normal volumes of urine but in the first few days developed severe oliguria, which proceeded to polyuria, the urine containing a high concentration of urea but a very low concentration of sodium and chlorine.

Case-reports

Case 1.—An electrical engineer, aged 28, was admitted on Dec. 3, 1955, with severe occipital headache, sweating, and photophobia. Six days before admission he had had an acute attack of diarrhœa lasting two days.

On admission he had neck rigidity, slight weakness of his legs, and blood-pressure 140/80 mm. Hg. Next day he was hoarse and had difficulty in coughing and weakness of his arms and legs.

Progress

On Dec. 5 his blood-pressure had risen to 195/90 mm. Hg, his bladder was distended, and 330 ml. of dark urine, withdrawn by catheter, was slightly acid and contained a trace of protein but no cells.

By Dec. 6 his breathing was difficult, tracheotomy was done, and a positive-pressure respirator was affixed. His general condition was poor, and during the day he had two attacks of cyanosis, the first being attributed to difficulty with the apparatus but the second to a cerebral vasomotor upset. His blood-pressure during these attacks fell temporarily to 80/30 mm. Hg.

From Dec. 6 to Dec. 8 his urinary output was very scanty —170, 140, and 240 ml., with intakes of 2300, 3000, and 3400 ml. of fluid, for the three days. His systolic blood-pressure during this time was 90–110 mm. Hg.

His urinary output increased from 1200 ml. on Dec. 9 to 5600 ml. on Dec. 13 and remained copious after this. His blood-pressure meanwhile was 170/110–190/120 mm. Hg. His urine remained acid and contained only a trace of protein, with a very few red cells and casts. By Dec. 16 his blood-pressure had returned to normal, and it remained thereafter about 130/90 mm. Hg.

His blood-urea level had remained high throughout in spite of apparently adequate urinary excretion, but his serum electrolyte levels rose, with the onset of diuresis, to Na 169 m.eq. per litre, K 5.9 m.eq. per litre, Cl 130 m.eq. per litre, and HCO_3 24.8 m.eq. per litre on Dec. 17.

On Dec. 19 I was asked to see him because of these electrolyte abnormalities. He was now practically completely paralysed in all his limbs, there being only slight movements of his right hand and forearm, and respiratory distress was caused during brief interruptions necessary to adjust the respirator.

Chemical Observations (figs. 1–3)

Period I (hyperchloræmic phase).—From Dec. 14 to Dec. 29 there were high serum-electrolyte levels, with very scanty urinary excretion of sodium and chlorine. The blood-urea level was high, and the urinary urea concentration was also usually high—up to 3.5 g. per 100 ml. The intake of fluids (mostly by intragastric drip) was 3300–4500 ml. a day and the volume of urine usually 1500–2000 ml. a day. Until Dec. 16 the diet had consisted of milk and eggs, with various supplements, containing about 100 m.eq. of sodium, 60 m.eq. of potassium, and 50 g. of protein daily; but, because of the rising serum electrolyte levels, a diet of fat and carbohydrate without electrolytes was given from Dec. 17, the total intake of fluids being kept at the same level. The blood-urea level had been falling, so 'Casilan' 50 g. and later 100 g. daily was added to the diet from Dec. 20 but stopped again on Dec. 28, when the blood-urea level rose. This rise was probably due to mersalyl (see below). Between Dec. 28 and Jan. 2, the serum-sodium and serum-chlorine levels fell and the blood-urea level returned to normal. This was associated with increased urea clearance and the excretion of 48 g. and 56 g.

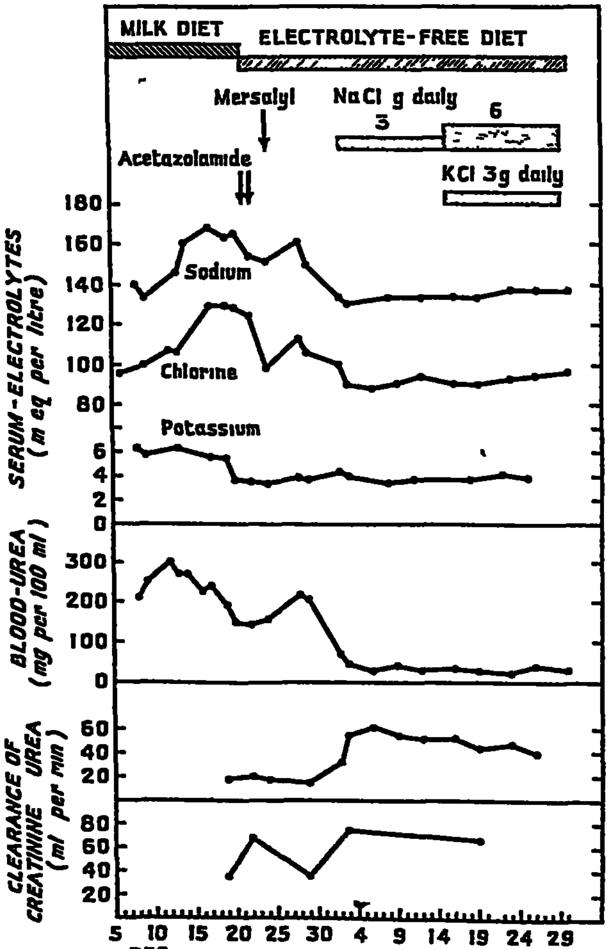

Fig. 1—Case 1: serum-electrolyte and blood-urea levels and clearance of urea and creatinine.

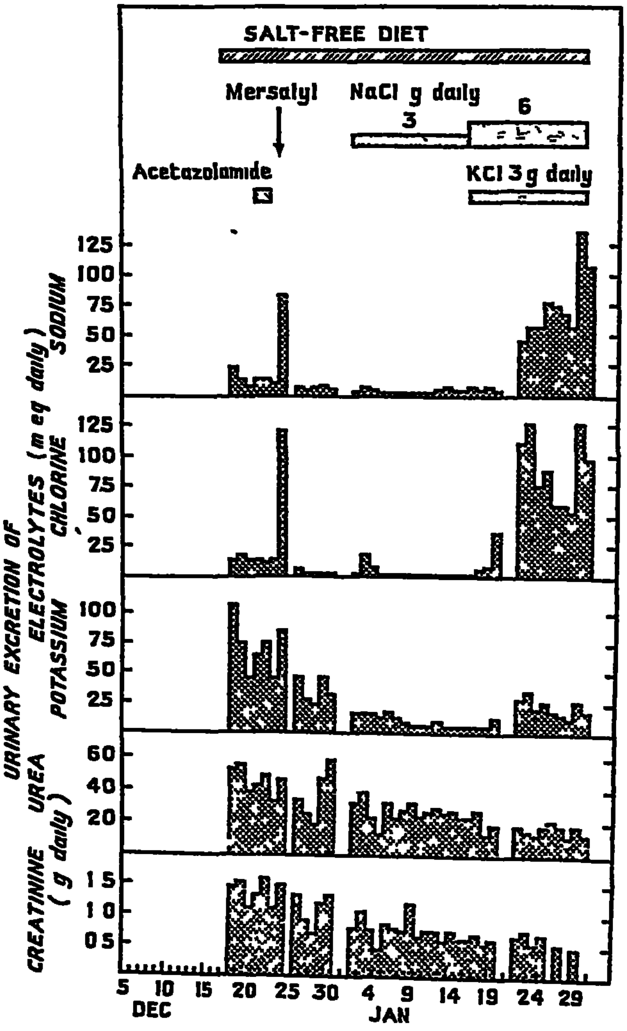

Fig. 2—Case 1: urinary excretion of electrolytes, urea, and creatinine.

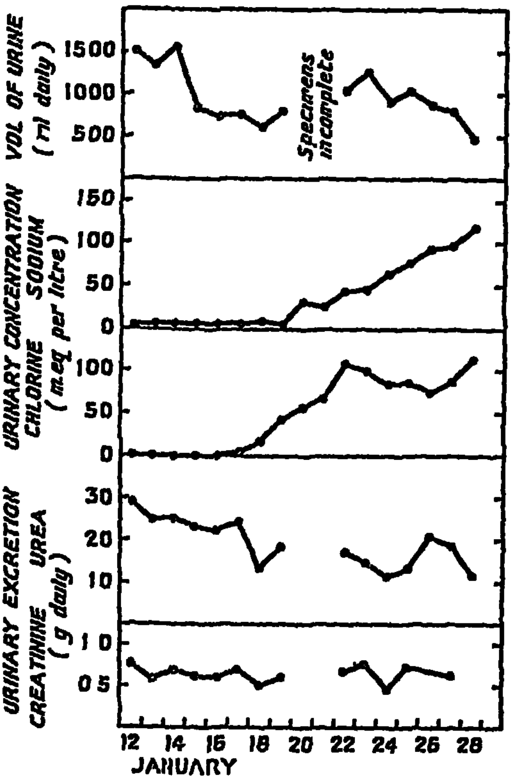

Fig 3—Case 1: resumption of excretion of electrolytes.

of urea on Dec 29 and 30, the output for the previous three days having been only 33 g, 25 g, and 19 g.

Period II.—From Dec 30 to Jan 16 the blood urea level was normal and the serum sodium level (about 134 m eq per litre) and the serum chlorine level (about 91 m eq per litre) on the low side of normal. The urinary urea concentration was usually 1·5–2·5 g per 100 ml. Salts were cautiously added to the diet (NaCl 3 g daily from Jan 3, later increased to 6 g daily, and KCl 3 g daily from Jan 15), but the excretion of sodium remained about 2–4 m eq daily, and, except for the two days immediately following the addition of NaCl to the diet, when 18 and 8 m eq were excreted, the excretion of chlorine was too scanty to be measurable—1 m eq or less daily. The excretion of potassium decreased from about 45 m eq daily at the beginning to 3–4 m eq daily at the end. It seems possible that this period covered the greater part of removal of waste tissues, the daily creatine output decreased from 1·65 g daily on Dec 29 to 0·32 g daily on Jan 17.

Period III (Jan 17–28).—The resumption of excretion of electrolytes on Jan 17 was preceded on Jan 15 by a sudden decrease in volume of the urine from 1200–1500 ml daily to 600–800 ml daily without change in the output of creatinine. The excretion of chlorine started on Jan 17 with a urinary concentration of 6 m eq per litre and increased continuously to 108 m eq per litre in six days. The excretion of sodium started on Jan 18 with 9 m eq per litre and continued to increase somewhat more slowly to 120 m eq per litre after eleven days. The excretion of potassium increased from about 5 m eq per litre to 25 m eq per litre. These results are shown graphically in fig 3.

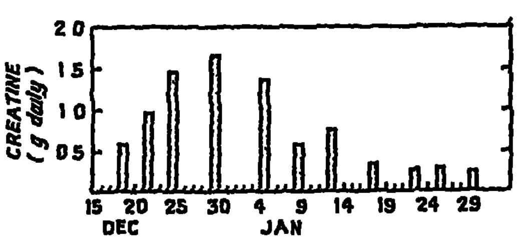

Fig 4—Case 1: urinary excretion of creatine.

Excretion of creatinine and creatine.—The excretion of creatinine fluctuated round about 1·2 g daily when observations were started and gradually decreased, as muscle mass decreased, to a mean of about 0·7 g daily by the end of the second month of illness. The excretion of creatine increased from 0·57 g on the fifteenth day of illness to a maximum of 1·65 g on the twenty-sixth day, and decreased to 0·32 g daily at the end of the seventh week. The findings are shown in fig 4.

Excretion of steroids.—The figures for the excretion of steroids are given in table I. The 17-ketogenic steroids and 17-hydroxycorticosteroids were determined by the methods of Appleby et al. (1955); the aldosterone was kindly estimated by Dr I. H. Mills, of St Thomas's Hospital, London. Although the first figures in both cases are above normal, they are probably not more than would be expected from the stress of the illness; and, when the excretion of steroids is expressed as mg per g of creatinine (if this is justifiable in a patient with gradually diminishing excretion of creatinine) the values on Jan 18, by which time the metabolism of Na and Cl had returned to normal, were at least as high as at the height of sodium retention. The aldosterone figure is definitely high: Dr Mills gives up to 2 µg daily as the upper limit of normal.

Effects of acetazolamide and mersalyl.—During the period of hyperelectrolytæmia the effects of acetazolamide and of mersalyl were investigated. Acetazolamide was given (250 mg on Dec 21 and 500 mg on Dec 22) without producing any change whatever in excretion of sodium and chlorine and producing only an insignificant change in excretion of potassium. Mersalyl 2 ml on Dec 24 increased the volume of urine from 1300 ml to 2650 ml and the excretion of sodium, chlorine, and potassium. The serum chloride level fell during the mersalyl day from 125 to 98 m eq per litre. The effect of the mersalyl is shown in table II. The excess fluid excreted was definitely hypotonic compared with the serum, and the net effect was disadvantageous and to increase dehydration: the blood urea level rose from 164 to 227 mg per 100 ml and the serum sodium level from 152 to 161 m eq per litre. Before the mersalyl was given, the urinary sodium and chlorine concentrations had been low, 6–12 m eq per litre representing the range of concentrations. After mersalyl diuresis they fell still lower to 1–7 m eq per litre and 0–3 m eq per litre respectively.

TABLE I—EXCRETION OF STEROIDS

Date	Daily excretion (mg)			Excretion expressed as mg per g of creatinine

O H C S, hydroxycorticosteroids.

Clinical Progress

By Jan 18 the patient had improved to the extent that he had fair strength in his right hand and forearm and a slight return of power in his left hand. His legs were still completely paralysed, and his respiration had recovered to the extent that he could breathe without the respirator without distress for 5–8 minutes.

His respiratory paralysis gradually improved slightly, and by the end of January he could breathe without the respirator for 45–60 minutes, but at this time he had little power except in his right hand and forearm and his left hand.

TABLE II—EFFECT OF MERSALYL ON DAILY EXCRETION

—	Water (ml)	Na (m eq)	K (m eq)	Cl (m eq)
Average of previous 3 days	1480	10	59	14
Mersalyl day	2650	84	85	120
Excess due to mersalyl	1170	74	26	106

Case 2—A woman, aged 40, was admitted on Jan 13, 1956, with a week's history of backache, pains in the legs, and severe frontal headache The day before admission she vomited several times and noticed weakness in both legs

On admission she was fully conscious and coöperative, with blood pressure 140/80 mm Hg, nystagmus, weakness of her left arm, and paralysis of both legs Her blood urea level was 34 mg per 100 ml, and her serum electrolyte levels were normal

Progress

Next day her left arm was completely paralysed, she developed severe dyspnœa for which tracheotomy and an intermittent positive pressure machine were needed, and her blood pressure was 160/90 mm Hg

On Jan 15 her blood pressure was 100/80 mm Hg and urinary output 1200 ml, but next day, with the same blood-pressure, the urinary output decreased to 60 ml For the next three days she was semiconscious, with blood pressure 100/80–130/80 mm Hg, her daily urinary output increasing again to 430, 1640, and 1480 ml After this her general condition deteriorated, her urinary output gradually diminished, and she died on Jan 24 without fully recovering consciousness

Chemical Findings

The blood urea level rose from 39 mg per 100 ml on Jan 14 to 310 mg per 100 ml on Jan 20 The serum electrolyte levels were still within normal range on Jan 20 (Na 143 m eq per litre, Cl 96 m eq per litre), but the electrolytes in the urine had decreased from Na 15–35 m eq per litre and Cl 6–10 m eq per litre during the first three days to Na 4 m eq per litre and Cl 0 on the sixth day During the whole of her illness the urinary concentration of potassium remained high—35–79 m eq per litre during the first three days and 53 m eq per litre on the day before death The urea concentration in the urine varied throughout from 1 2 to 1 85 g per 100 ml

Discussion

Lower nephron nephrosis has been suggested by Schoolman et al (1955) as a possible cause of this chemical syndrome, but the picture differs from the diuretic phase of lower-nephron nephrosis in nearly every respect, in lower nephron nephrosis the tubules have lost their concentrating power and manifest this by excretion of a near glomerular filtrate, with a low urea concentration and usually a high electrolyte concentration In complete contrast the present patients had a very high concentration of urea with a very low sodium and chlorine content of the urine, showing that there was excessive reabsorption of sodium and chlorine

Dehydration

The simplest explanation of the chemical changes would be to regard the initial polyuria as an osmotic diuresis caused by the large amount of tissue breakdown products to be excreted, thus leading to dehydration, and to regard the absence of salt from the urine as due to salt deficiency, but this explanation encounters many difficulties

Many patients with hyperelectrolytæmia have been in coma, or with diminished thirst sensation, and Welt et al (1952) have shown that dehydration is a common cause of the condition In some of the many cases described by Schoolman et al (1955) dehydration was probably responsible

Although some dehydration was present and there was thirst during the hyperchloremic phase the present cases differ from cases of simple dehydration in the extremely scanty urinary excretion of Na and Cl McCance et al (1944) by simple dehydration in healthy persons, cut down the volume of urine from 1 34 ml a minute to 0 43 ml a minute with an increase in urinary urea from 1 04 to 3 98 g per 100 ml and an increase of urinary chloride from 86 to 219 m eq per litre Nadal et al (1941) by water deprivation in a person on a salt deficient diet, found urinary chloride values of 35 and 19 m eq per litre only when gross salt deficiency was produced by intestinal suction in an already salt deficient patient did the urinary sodium and chlorine fall to really low values, and this was associated with very low values of the electrolytes in the serum

McCance et al (1944) produced an osmotic diuresis in a dehydrated person by giving urea 35 g intravenously, the urinary sodium decreased from 125 to 17 m eq per litre as the urea increased from 2 9 to 4 8 g per 100 ml, but this amount of urea is very much more than was observed in either of the present patients, and the depression of urinary electrolytes very much less in case 2 the urinary urea increased only to 1 85 g per 100 ml the day before death, at which time the urinary Na was 7 m eq per litre and the urinary Cl 0 Unfortunately the total osmolar concentration was not determined

The abnormal tubular reabsorption in these patients was not confined to sodium and chlorine In another patient (not described here), who had very high serum-sodium and serum-chlorine levels with adequate urinary volume but negligible urinary concentration of these ions, sodium thiosulphate was given intravenously The glomerular filtration, calculated from endogenous creatinine, was about 160 ml a minute, but the thiosulphate "clearance" worked out at 2 2 ml a minute, showing that this foreign ion was also being abnormally reabsorbed

The distribution of fluid and electrolytes between the various body compartments may be disturbed, and Borst (1938, 1948) considers that the hyperelectrolytæmia observed from time to time after massive gastro-intestinal hæmorrhage is due to a diminution in volume of the circulating blood, and that this is responsible for the excessive renal reabsorption of sodium and chlorine, notwithstanding that there may sometimes be an excess of total extracellular fluid, even to the extent of œdema Borst (1951) has suggested that the findings in head injury are due to the diminished volume of circulating blood, but this is disputed by Higgins et al (1954)

In case 1 there was evidence of hæmoconcentration, the hæmoglobin increasing from 100% on admission to 106–108% during hyperelectrolytæmia The subsequent decrease to about 80% at the end of the hyperosmolar period was probably partly due to hæmodilution, but the effect of the infection in causing anæmia cannot be ruled out

The effect of mersalyl affords support for the theory that the diminished volume of circulatory blood is a factor the day mersalyl was given the blood-urea level had fallen to 150 mg per 100 ml and the serum sodium level to 154 m eq per litre After diuresis, with the loss of about 1200 ml of water, these levels rose again to 227 mg per 100 ml and 161 m eq per litre Borst and de Vries (1950), however, observed practically no response to mercurials in the patients with the syndrome due to a small volume of circulating blood

The blood electrolyte levels are related to changes in renal function The glomerular filtration rate, measured by endogenous creatinine clearance, rose from 35 ml a minute on Dec 19 to 69 ml a minute on Dec 22, as the serum sodium and serum chlorine levels were falling After mersalyl the creatinine clearance decreased again to 34 ml a minute on Dec 29, and the serum sodium and blood urea levels rose During the next four days, when the serum electrolyte levels fell to normal values the creatinine clearance increased to 79 ml a minute and the urea clearance to 36 ml a minute Throughout there was an inverse relationship between creatinine clearance and the levels of sodium, chlorine, and urea in the blood

During the four days from Dec 28 to Jan 2 the serum sodium level fell from 161 to 131 m eq per litre and the serum chlorine level from 112 to 92 m eq per litre These falls were not associated with any significant urinary excretion of electrolytes and must have been due to either dilution through expansion of the body-fluids or redistribution of fluids (and electrolytes) within the body Although the available data are insufficient for a definite decision between these alternatives, the second seems the more probable Even with as low a figure as 30 litres for total body water this dilution of 18% would mean a retention of 5 5 litres of water during the period Although urinary collections were incomplete during two days, there was no indication in the output of urine or in the intake of fluids to suggest such a retention

Although data of the output of salt during the first fortnight of illness are not available, the suggestion of salt deficiency might be regarded as supported by the fact that practically no chlorine and negligible sodium were excreted during a period in which 48 g of salt (820 m eq) was administered, but the findings differ from an ordinary salt deficiency in the intensity of the retention Further, in cases of severe salt deficiency the excretion of small quantities of sodium and chlorine usually begins almost as soon as salt is administered and long before a gross salt deficiency has been remedied The serum sodium (134–139 m eq per litre) and the serum chlorine (90–94 m eq per litre) were slightly low, but the return of chlorine and sodium to the urine was not associated with any significant change in these levels on Jan 19, by which time the urinary concentration of chlorine had increased to 41 m eq per litre, the serum-chlorine was still only 90 m eq per litre

The importance of potassium deficiency in poliomyelitis has been emphasised by Lans et al (1951) and Hall and Sherman (1953), and it might be suggested that the renal abnormality was due to potassium deficiency It is true that the excretion of electrolytes started again shortly after potassium chloride had been given, but this was probably merely coincidental the amount given before chlorine reappeared in the urine was only 6 g of KCl (80 m eq of potassium), and this quantity is quite insufficient to have significant effect on a real potassium deficiency

Antidiuretic Hormone

The association of hyperelectrolytæmia with diabetes insipidus has been well worked out by Engstrom and Liebman (1953) In one case of anterior and posterior pituitary deficiency following pregnancy the patient always had high levels of sodium and chlorine when not receiving vasopressin The values fell to normal when vasopressin was given, and the concentration, but not the total amount, of urinary sodium and chlorine increased In the case published by Peters (1948) of hyperelectrolytæmia following operation on a craniopharyngioma and in the cases published by Cooper and McCarty (1951) there was evidence of a postoperative acute diabetes insipidus

The possibility of interference with the production of antidiuretic hormone needs consideration in the present cases also In case 1 the early polyuria might have been due to lack of antidiuretic hormone, thus leading to dehydration, and excessive production of aldosterone (cf Bartter et al 1956, Muller et al 1956), the failure to excrete sodium and chlorine would then be due to continued excessive production of aldosterone It has been pointed out that the return of electrolyte excretion in the urine was preceded by a sharp diminution in the volume of urine (fig 3) Could this be due to a return of antidiuretic hormone and an associated decrease in aldosterone activity ? This cannot be regarded as proved but gives suggestions for further work

Kriss et al (1948) and Kaplan and Rapaport (1951) have shown that the excretion of sodium and chlorine is also controlled by the action of the splanchnic nerves on the renal tubules It is, of course, possible that some alteration in splanchnic activity is concerned in this syndrome, but there is no way of demonstrating this

Whatever the final decision about the cause of this condition, there are definite lessons for the management of severe cases of poliomyelitis, particularly in the severe bulbar form The serum electrolyte levels should be watched If the serum sodium and serum chlorine levels rise, salt should be discontinued and additional fluid given (The fluid intake in case 1 in the early stages was probably insufficient) When the serum electrolyte levels return to normal, salt should be added cautiously, but perhaps more rapidly than in case 1, and the possibility of a potassium deficiency must also be borne in mind

Astrup et al (1954) found serum sodium and serum chlorine levels usually normal or low in poliomyelitis Probably this hyperelectrolytæmia is a comparatively rare complication of poliomyelitis, but its existence, with the cessation of urinary excretion, makes the determination of serum-electrolyte levels necessary and emphasises the danger of relying solely on observations of urinary excretion by the Fantus test

Summary

Two cases of bulbar poliomyelitis showed a nearly complete suppression of urinary excretion of sodium and chlorine One of them also showed gross hypernatræmia and hyperchloræmia

Excessive excretion of aldosterone was present in one of the cases Reasons are given for considering that this chemical syndrome is due to some cause other than simple dehydration

These chemical changes may have been associated with interference with secretion of antidiuretic hormone, the consequent polyuria and dehydration may have led to the increased production of aldosterone, which in turn may have been responsible for the retention of sodium and chlorine

My thanks are due to Dr J P Marsden for allowing me to investigate the cases, Dr H G Close and the laboratory staff at Joyce Green Hospital for much assistance, Sister G Sims for her care in collecting specimens, and Mr P J Hawker and Mr J W Moreton for most of the analyses

AMIPHENAZÓLE IN A CASE OF DRUG ADDICTION

IAN D BALLANTINE
M B Glasg
TUBERCULOSIS PHYSICIAN, LAW HOSPITAL, CARLUKE

THE dangers of narcosis and respiratory depression have often prevented the full use of the pain-killing qualities of the opium alkaloids, and the risk of addiction is another bar to their continued administration Amiphenazole (2 4 diamino 5 phenylthiazole hydrochloride) has recently been found to stimulate the respiratory centre The concurrent administration of amiphenazole and morphine abolishes the depressant action of morphine on respiration (Shaw and Bentley 1955) Larger doses of morphine (200 mg) can safely be administered, so that the maximum analgesic action is obtained but respiratory depression is slight Moreover, the vomiting and constipation sometimes caused by morphine are often abolished when it is given with amiphenazole

The successful treatment of pethidine and 'Omnopon' addiction by amiphenazole has not yet been reported in this country

Case-report

A married woman of 26 fell ill with pulmonary tuberculosis in 1943 After hospital treatment she recovered and remained well until November, 1953, when she had an attack of pneumonia She was admitted to hospital in April 1954, with very extensive bilateral pulmonary tuberculosis with large thick walled cavities Under treatment with anti tuberculosis drugs there was some improvement Drug resistance developed and improvement was not maintained

In June 1956, she began to have repeated daily hæmoptyses and severe chest pain Her condition then steadily deteriorated and the prognosis became hopeless Pethidine gave some relief, but the symptoms were effectively controlled only by morphine Later, owing to gastro intestinal upsets, omnopon was given instead During the next four months she was given on an average 200 mg of omnopon and 300 mg of pethidine daily

The patient was depressed and confused, anorexia was extreme and she became even more emaciated Peripheral œdema developed She was persistently cyanosed even with almost continuous oxygen therapy During this time the patient became an obvious addict and demanded injections as soon as the effect of the previous one was wearing off, pleading pain, although we were seldom convinced of its presence

On Nov 17 we began treatment with morphine and amiphenazole During the next three days she was given a total of 2 842 g of morphine subcutaneously and 1 06 g of amiphenazole orally There was an immediate change in her condition She became mentally bright and alert, cyanosis disappeared her appetite improved and the œdema subsided Apathetic for months, she now became anxious to try a new antituberculosis drug and moved around freely in bed

For the next ten days no morphine was given The patient had no desire for further injections and required no sedation apart from a short-acting barbiturate at night Since then a small dose of morphine (16 mg) covered by amiphenazole (20 mg) has been required occasionally for obvious severe pain She now dislikes these injections, which is in marked contrast to her previous attitude

Comments

This patient had obviously become addicted to omnopon and pethidine This addiction was rapidly cured by amiphenazole without any withdrawal symptoms

It may be that amiphenazole should be given concurrently during prolonged medication with an opium alkaloid or the synthetic analgesics, pethidine and methadone hydrochloride Further investigation into the value of amiphenazole in the prevention and cure of addiction might be profitable

Preliminary Communication

ERYTHROCYTE-POTASSIUM LEVEL IN RHEUMATOID ARTHRITIS

THE administration of adrenocortical steroids in man results in a net loss of potassium from the body and lowers the level of intracellular potassium Streeten and Solomon[1] have shown that the administration of corticotrophin or cortisone does not lower the potassium content of the erythrocytes but probably raises it Their investigations suggest that, as regards their content of potassium, the behaviour of erythrocytes towards adrenal steroids differs from that of other body cells

Sherwood Jones[2] investigated the distribution of electrolytes between erythrocytes and plasma in 3 patients with Addison's disease and in 2 patients with Cushing's syndrome They reported, however, normal levels of sodium and potassium in the erythrocytes

In view of a possible association between the adrenal steroids and the erythrocyte-K^+ level and the association of the collagen group of diseases with adrenal steroid metabolism, we decided to investigate the erythrocyte-K^+ levels of patients with collagen diseases

We report here the initial results obtained in patients with rheumatoid arthritis

METHOD

A simple standardised procedure was adopted suitable for routine laboratory analyses Estimations of the erythrocyte-K^+ level were based upon an indirect method requiring the determination of the whole blood K^+ level, the plasma-K^+ level, and the hæmatocrit reading Heparinised venous blood was used for the determinations The estimations were undertaken with as little delay as possible, and provided they were carried out within four hours of venepuncture, there was no significant loss of cell K^+.

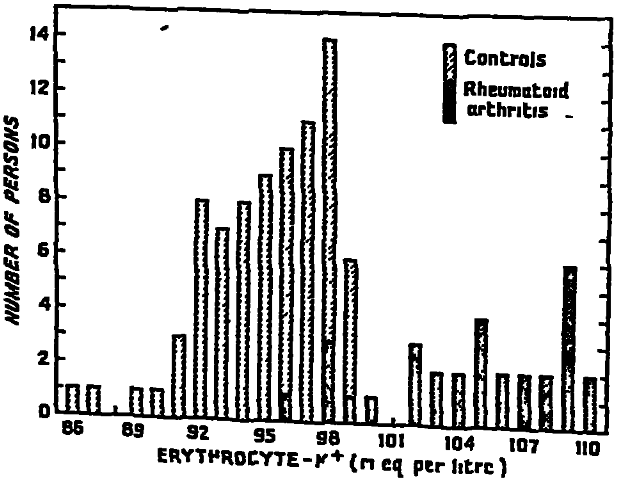
The whole blood K^+ was estimated in duplicate, the samples being prepared by diluting whole blood 1 in 1000 with distilled water The maximal acceptable deviation between duplicates was 0 5 m eq per litre for whole blood Flame photometer standards containing the appropriate sodium "background" gave complete linearity of scale over the working range of K^+ values

Plasma K^+ was estimated on 1 in 100 dilutions of plasma Hæmatocrits were determined in Wintrobe tubes by centrifuging for thirty minutes at 3000 r p.m in a governor-controlled centrifuge

SUBJECTS INVESTIGATED

The erythrocyte-K^+ level was investigated in the following groups

(1) "Controls" composed of medical students of either sex and patients with diseases other than of the collagen group or conditions known to be associated with electrolyte disturbance



---

[1] Streeten D H P Solomon, A K *J gen Physiol* 1954 37 643
[2] Jones E S *Nature Lond* 1955 176, 269

(2) Patients of either sex with "active" or "quiescent" rheumatoid arthritis None were on steroid therapy

RESULTS

The distribution of erythrocyte-K^+ levels in the 80 "controls" is shown in the accompanying figure None of the "controls" had an erythrocyte K^+ level higher than 99 m eq per litre The distribution of erythrocyte-K^+ levels in 31 women with rheumatoid arthritis is also shown in the figure In this group 5 patients had erythrocyte-K^+ levels below 100 m eq per litre and 26 had 100 m eq per litre, or more Of 12 men with rheumatoid arthritis (see table) 3 had erythrocyte K^+ levels within the range of figures obtained for the "controls."

12 CASES OF RHEUMATOID ARTHRITIS IN MALES

Case no	Age (yr)	Erythrocyte K^+ level (m eq per litre)
1	30	98
2	55	101
3	44	104
4	53	106
5	46	107
6		104
7		105
8	66	98 5
9	50	100
10	65	102
11	60	98 5
12	66	106

No correlation was found between hæmatocrit reading, cell size, hæmoglobin content, age of patient, and erythrocyte-K^+ level

Clinical assessment of the patients suggested that the erythrocyte-K^+ level may be related to the degree of activity of the disease

CONCLUSIONS

The results obtained in this preliminary series indicate that patients with rheumatoid arthritis tend to have erythrocyte-K^+ levels higher than the accepted normal range The finding may be more constant in females than in males

The cause of the raised erythrocyte K^+ level is unknown Among other hypotheses, possible alterations in steroid metabolism, and their effects on the permeability of the erythrocyte, are being considered

A larger series of patients and a series of matched controls are under investigation in conjunction with the department of physical medicine of the Middlesex Hospital It is intended to study the relation of erythrocyte-K^+ levels to activity of disease and to steroid metabolism, and to assess the value of the investigation in the diagnosis of rheumatoid arthritis and the ability of the test to differentiate this disease from similar conditions

Our thanks are due to Dr A C Boyle and Dr. D Mattingl for referring patients to us and for their clinical assessment of the cases, and to Sir Charles Dodds for his interest in the work.

Medical Societies

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

Toxoplasmosis

THE society met in London on Jan 17, with Prof R M GORDON, the president, in the chair, to discuss Toxoplasmosis

Prof P C C GARNHAM said that the prevalence of toxoplasma infection in man has been put as high as 50% in some communities, on the basis of serological tests, of which the dye test is the commonest The validity of this test has been doubted, and possibly man may acquire antibodies to sarcocystis passively from cattle, sheep, and pigs, which are commonly infected with that organism, such antibodies may give a positive reaction in the dye test for toxoplasma

Prof C P BEATTIE said that severe and fatal forms of toxoplasmosis first attracted notice, but these are rare Mortality in severe congenital forms is high, and children who survive are often mentally retarded, but it seems likely that even in congenital infections severe disease is the exception In the acquired disease the commonest manifestation is lymphadenopathy, with or without fever, and this may be mistaken for glandular fever except that the Paul Bunnell test is negative

The mode of transmission of the *infection to man* is unknown Many species of birds and mammals (including dogs and cats) have it, and tests indicate that persons handling animals are particularly prone to get it, no evidence of insect transmission has been found Man may become infected from man, or from imperfectly cooked meat No doubt there are many sources of infection, and transmission probably takes place by several routes

Dr I A B CATHIE said that it has been claimed that infection with *Trypanosoma cruzi* and trichomonas may give false positive dye tests, but he has not found this to be so, and has not encountered false positive complement-fixation tests in malaria or *Salmonella typhi* infections. Inactivation at 56°C for 30 minutes does not reduce the titre of the dye test antibody in human serum, and these antibodies, therefore, cannot be identified with properdin, but the sheep antibody is inactivated at 56°C, and therefore differs from the human antibody

Dr R LAINSON cited published work on the prevalence of this infection in animals, assessed by serological tests or isolation of the organism Isolation is the only sure proof of infection, and, since toxoplasma has not yet been cultivated on media free from living cells, isolation requires passage to "clean" laboratory animals Intraperitoneal inoculation of mice with brain tissue is convenient and satisfactory The morphology of strains isolated (there is only one species of toxoplasma) is uniform, and the strains are serologically and immunologically similar, though they may vary greatly in virulence Dr Lainson reported isolations from weasels ferrets, polecat ferret hybrids, and rats in England The carnivores may become infected by eating infected flesh possibly that of rabbits It appears that toxoplasma is a benign and well adapted parasite

Prof R J V PULVERTAFT showed a film of toxoplasma invading living cells or being phagocytosed by them

Dr J K A BEVERLEY remarked that a dye test of titre 1 in 500 or a complement fixation test of 1 in 16 may be taken as indicating active infection A rising titre is important, but the rise is not rapid A weak complement-fixation test may indicate old infection, and active infection can occur with a weak dye test, though subclinical infection can provoke high titres There is some evidence that pyrimethamine, the sulphonamides, and the sulphones are useful in treatment of the disease in animals

Dr J D FULTON described his method of isolating the organism for metabolic studies, glucose is the chief material used by it

Colonel J H WALTERS cited evidence which suggests that toxoplasmosis may be widely endemic in West Africa and said that it gives rise to a syndrome which may be mistaken for glandular fever

Dr BEVERLEY reported a laboratory infection from a contaminated hypodermic needle Dr CATHIE reported the case of a laboratory worker who had worked with toxoplasma for several years without the dye test becoming positive, and then suddenly the test became positive without the patient having had any illness or any other event which could explain it

THE RENAL ASSOCIATION

Azotæmic Renal Osteodystrophy

AT a meeting of this association on Jan 24, Dr S W STANBURY insisted that the clinical and biochemical investigation of the problems of azotæmic renal osteodystrophy should be based on a firm knowledge of the pathological state of the skeleton Neglect of histological study, which could often be made on biopsy specimens, had led to several serious misconceptions It was, for instance, universally assumed that osteitis fibrosa was the only osseous complication of uræmia in the adult By reference to the clinical and histological findings, in particular adult patients with chronic uræmia he was able to demonstrate both the development of florid osteomalacia and its presumptive cure by large doses of the vitamin D steroids Histological preparations of rachitic metaphyses were shown to support the claim that the uræmic child could develop true rickets This was certainly "rickets" when considered from the osteologist's viewpoint as "a failure of mineral deposition to keep pace with the endochondral growth of bone" Turning to the possible ætiology of the defective mineralisation, Dr Stanbury pointed out that the azotæmic patient wasted neither calcium nor phosphorus in the urine, but the intestinal absorption of both was defective As was the case with vitamin-D-resistant rickets (osteomalacia), this defect could be overcome by large doses of either calciferol or dihydrotachysterol, although the dangers of overdosage were considerable During successful treatment, calcium and phosphorus were retained in a ratio of approximately 2 to 1, and the osseous lesions were seen to heal radiologically Healing was accompanied by an increase in the level of blood citrate Reasons were given for believing that the metabolic defect represented an acquired insensitivity to vitamin D, for which it was unlikely that either systemic acidosis or elevation of the serum-phosphate could be held responsible A similar defect could occur in patients with lowered rates of glomerular filtration but without azotæmia, and also in nephrotic children No cause could be offered for the vitamin D resistance but it did not appear to be due to a simple failure to absorb the vitamin

The other osseous lesion occurring commonly in azotæmia was osteitis fibrosa, it could occur together with osteomalacia or independently The osseous changes were indistinguishable from those of primary hyperparathyroidism and, as in that condition, the presence of osteitis fibrosa was always accompanied by a reactive or reparative formation of new bone Clinically, renal osteitis fibrosa was best and earliest seen in the finger radiograph as erosions or ' scalloping" of the cortical surfaces of the phalanges It was probable to the point of certainty that a functional hyperparathyroidism was responsible for these lesions, but there was little direct evidence to indicate the cause of this secondary change From his personal experience of the condition, Dr Stanbury had two observations to make First, that the patient need not have rickets or osteomalacia prior to the development of hyperparathyroidism Secondly, one could not safely assume that the production of a positive calcium balance or even of hypercalcæmia would lead to regression of the parathyroid hyperplasia This may conceivably happen in some patients after vitamin D therapy, but in others hyperparathyroidism would continue and the lytic processes of osteitis fibrosa would release mineral from the recalcified skeleton This in turn could lead to extreme degrees of metastatic calcification

Prof C E DENT said that little had been added to our knowledge of this condition since Liu and Chu had described the major defect as being an inability to absorb calcium from the gut, with a negative calcium balance due to fæcal rather than urinary losses This resembled vitamin-D deficiency, but they had found that this vitamin did not correct the rickets or reverse the calcium balance, though A T 10 did. (The dose of A T 10, however, had been relatively much greater) Professor Dent had fully confirmed these findings but had found that calciferol could produce as good a response as A T 10 if given in corresponding amounts In one case he described in detail, the plasma-phosphorus rose but the calcium fell in spite of a strong positive balance, the urinary phosphate excretion rose with the plasma level, but the balance of phosphorus also became positive In azotæmia, pure rickets could occur with no evidence of osteitis fibrosa at necropsy, even when the essential renal lesion was glomerular The type of bone disease was therefore independent of the renal lesion It was usual to ascribe it to acidosis but giving alkalis with vitamin D produced no effect beyond that of the vitamin alone Renal hyperparathyroidism always responded equally well to this treatment, and this may be seen in as little as three weeks In one case, osteitis fibrosa healed but the renal rickets got worse, this was apparently due to a phosphate deficiency brought about by treatment with aluminium hydroxide, for it rapidly healed when this was stopped Another type of bone lesion seen was osteosclerosis

All three types of bone lesion seen in renal failure could also be seen in steatorrhœa, and resistance to vitamin D could then be demonstrated even when it was given parenterally It was possible that some anti vitamin-D factor was circulating in renal failure, as was originally suggested by Liu and Chu Such a substance might, like cortisone, partly reverse the action of vitamin D With adequate vitamin D therapy renal osteodystrophy always improved spectacularly even at a time when renal failure was progressing

Reviews of Books

Hearing Defects in School Children

Scottish Council for Research in Education (publication no 38) London University of London Press 1956
Pp 110 10*s* 6*d*

THIS excellent monograph records very carefully the results of an investigation into hearing defects in children, mainly at ordinary schools

The authors stress the great importance of standardising the techniques of audiometry Most of the screening tests in ordinary schools have, unfortunately, to be carried out in a considerable level of background noise, but noises of up to 45 decibels can be present without affecting the threshold of hearing at any of the "speech" frequencies This noise level should be regarded as the maximum permissible in testing, even if the earphones are well designed

In attempting to correlate the degree of hearing loss with educational attainment, the committee found that a group of 12-year-old children with average hearing losses of over 20 decibels were retarded by 8 or 9 months in comparison with a corresponding control group of normally hearing pupils They concluded that even slight or moderate defects of hearing could constitute a serious educational handicap and that quite severe deafness had commonly escaped the notice of teachers Since many of these children could be cured or relieved by treatment, and since the educational handicap could be minimised by appropriate attention (even when medical treatment failed), audiometric testing of every child should be regarded as essential The wisdom of these conclusions will be evident to anyone who reads the text in full

Roentgen Signs in Clinical Diagnosis

ISADORE MESCHAN, M A, M D, professor and director of department of radiology at the Bowman Gray School of Medicine of Wake Forest College, Winston Salem North Carolina, U S A Philadelphia and London W B Saunders 1956 Pp 1058 £7

In this book of little more than a thousand pages, the author has provided a comprehensive survey of nearly every aspect of diagnostic radiology, and has in addition included chapters on radiographic techniques and radiation protection He has achieved this remarkable concentration of material by great economy of words in the text and by copious use of line drawings and diagrams in place of radiographs

In arrangement the work follows the pattern which is becoming increasingly popular in radiological textbooks—namely, of describing radiographic appearances, and then discussing the probable causes This method works well when the objective radiographic signs are clear and the possible causes few, but otherwise it may lead to confusion and repetition This danger, of which the author is obviously aware, is especially evident in the chapters on diseases of bone

This textbook will almost certainly become a standard work

Doctors in the Air

Wing Commander ROBERT MAYCOCK, A F C London Allen & Unwin 1957 Pp 145 15*s*

Doctors entering the Royal Air Force learn something of the stresses to which people who fly may be subjected, and during a short introductory course in aviation medicine at Farnborough see some of the many facets of the subject Probably few others appreciate the number of factors which must be reckoned with to ensure safety and even survival in the air

Wing Commander Maycock opens with a brief historical sketch of aviation, and logically progresses to problems of oxygen lack at altitude, *g* stress, and escape from high speed aircraft Chapters of autobiography indicate the wide range of the author's Service activities, and lead to discussion of further problems such as fatigue in aircrew and transport of casualties It is apparent how widely " applied physiology " enters into the design of a great deal of flying equipment, but technicalities are kept to a minimum

Though partly a personal narrative, the book clearly describes some of the important problems which had to be solved before man could safely fly fast and high, and it will bring to many readers some idea of the wide field covered by aviation medicine

La kinésithérapie dans le traitement des algies vertébrales

L CHARRIÈRE, professeur d'éducation physique, kinesitherapeute des Hôpitaux de Lyon Paris Masson 1956 Pp 156 Fr 1200

WITH the increasingly conservative attitude towards backache of all descriptions, the physiotherapy departments are taking an ever greater part in its treatment This unpretentious little book gives clear instructions on how exercises and postural therapy can be applied to these conditions The many diagrams are simple and to the point, although that of spondylolisthesis is incorrect and on the purely medical aspects the author is frequently open to criticism In his own field he is excellent, and physiotherapists will find this book worthy of study

The Human Machine

An Analysis and Description of the Human Body, and its Structure and Functions, in Terms of Inanimate Machinery

Sir ADOLPHE ABRAHAMS Harmondsworth Penguin Books 1956 Pp 200 3*s* 6*d*

It is the human machine in athletic activity which the author has really at heart, and the motor-car is the machine with which he compares and contrasts it The book will thus appeal chiefly to athletes and the athletically minded, who should find it instructive, illuminating, and salutary, with its ingenious analogies, its athletic erudition, and the cold douches of fact and common sense sprayed upon hoary myths and superstitions It seems odd to postulate " Nature " as the purposeful designer of the human frame and at the same time write off our hopes and fears as activities of our central nervous systems, but perhaps philosophy should be left to philosophers

---

Blood Transfusion in Clinical Medicine (2nd ed Oxford · *Blackwell Scientific Publications* 1956 Pp 58[illegible] 45*s*)—The appearance of a second edition of this book by Dr P L Mollison will be welcomed by those in any way concerned with blood transfusion This edition will enhance the reputation quickly and deservedly won by the book when first published in 1951 The developments since then—in many of which Dr Mollison has himself had a hand—have necessitated extensive revision and the introduction of much new material One feature which distinguished the first edition has fortunately not been lost—the greater part of the book is based on the author's personal experience This work can be highly recommended

Diseases of the Heart (2nd ed Philadelphia and London W B Saunders 1956 Pp 1161 6 guineas)—The second edition of this well known textbook by Dr Charles K Friedberg maintains the high standard set by the first Three new chapters on graphic methods of cardiovascular examination have been added, and the section on cardiac surgery has been extensively revised to include the latest advances in surgery under direct vision, such as pump oxygenators, and hypothermia The book is up to date, and the exhaustive bibliography at the end of each chapter adds greatly to its value The author scrupulously gives a balanced picture on many controversial matters, commonly adding his own summing up This work is of great value to students and senior practitioners alike

Modern Operative Surgery (4th ed London Cassell 1955, vol 1, pp 1229 70*s* 1956, vol. 2, pp 2614 75*s*)—Many British surgeons were brought up on this work by the late Prof G Grey Turner Being accustomed to it they will be glad to greet the new edition, edited by Prof Lambert Rogers, as an old friend whose face has changed little The prefix " modern " should not, however, be allowed to mislead young surgeons Doubtless in an endeavour to present operative surgery over an era, procedures now outmoded are still described, though greater emphasis on current practice might be an advantage Perhaps future editions, of which there are likely to be many, will provide better illustrations and a fuller and more representative bibliography

Cardiopathies congénitales (2nd ed Paris Expansion Scientifique Française 1956 Pp 448)—The first edition of this comprehensive work by Prof P Soulié appeared in 1951 The author and his collaborators have now revised the text and added new chapters on scalar and vector cardiography, aortico pulmonary fistula, aortic stenosis, and arteriovenous aneurysms of the lung The book is in three parts The opening chapter of the first part deals with embryobiological anatomy, the second and third chapters with cardiac catheterisation and angiocardiography respectively There is a complete chapter devoted to cardiac shunts, cyanosis, and classification of the congenital cardiac anomalies The chapters in the second half of the book deal individually with the different forms of congenital heart disease The third part of the book is devoted to anæsthesia and surgical techniques, including cross circulation methods, pump oxygenators, and hypothermia This excellent and well illustrated textbook should be of great value to all students of congenital heart-disease

Nature of Viruses (London J & A Churchill 1956 Pp 292 42*s*)—The proceedings of the symposium on the biophysics and biochemistry of viruses held in London in March, 1955, under the chairmanship of Sir Charles Harington F R S, have now been published The editors for the Ciba Foundation, which organised the symposium, are Dr G E W Wolstenholme and Miss Elaine Millor

Hypotensive Drugs (London and New York Pergamon Press 1956 Pp 222 50*s*)—A conference on these drugs and the control of vascular tone in hypertension was held at the Wellcome Foundation, London, last April The proceedings have now been published under the editorship of Dr Michael Harington

THE LANCET

LONDON SATURDAY FEB 2 1957

Prognosis of Congestive Failure in the Elderly

Congestive heart-failure is one of the commonest reasons for the admission to hospital of people over the age of 65 In the absence of co-existing disease unrelated to heart-failure considerable and often dramatic improvement usually follows the application of the accepted principles of treatment for congestive failure at all ages, especially when it is coupled with an attack on any known underlying cause, such as anæmia, thyrotoxicosis or exacerbation of chronic respiratory infection It has long been apparent that if old patients could all receive the best standard of hospital care then the prognosis of congestive heart-failure would not be so poor as it is generally held to be

Bedford and Caird[1] point out that little has been written about the prognosis of congestive failure in the elderly, and they have made a detailed study of the condition in 231 patients of 65 or over, who represent 14% of all admissions to the geriatric unit at Cowley Road Hospital, Oxford during the forty-six months from July 1 1949, to April 30 1953 The patients were divided into nine ætiological groups normotensive hypertensive, aortic, rheumatic pulmonary, syphilitic thyrotoxic, anæmic and miscellaneous In considering patients of this age myocardial ischæmia was presumed to be a constant ætiological factor "Normotensive" meant normal blood-pressure and no evidence of any of the conditions in the other groups Thus, the underlying cause of failure was myocardial ischæmia alone for it was impossible to assess the contribution of precipitating factors in any group because many patients were too ill to give a reliable history 229 patients were successfully followed for one and two years, 162 patients for three years and 92 for four years and the corresponding survival-rates were 36% 27% 20%, and 16% These figures are impressive but as Bedford and Caird remark the outcome of a single episode of congestive failure is probably even better than these findings indicate since any hospital series is heavily loaded against survival because it contains many examples of recurrent or resistant failure and a high proportion of patients with some other lethal disease which determines the prognosis Some of the prognostic conclusions which Bedford and Caird have derived from their analysis seem at first sight to conflict with orthodox teaching Thus if an elderly patient survives an episode of congestive failure and the few months that follow it his expectation of life is not materially shortened Though 64% of the deaths took place in the first twelve months after the initial failure the expectation of life of those patients who survived for a year was at least equal to the normal, and moreover the age of the patient was not of prognostic significance In view of these findings it is obviously important to tackle with vigour the first bout of congestive failure in an old person and not simply to regard it from the onset as "terminal cardiac failure" Again as a generalisation, the prognosis in failure does not depend on the cause of the heart-disease For example the poor prognosis formerly accorded congestive heart-failure due to calcareous aortic stenosis is shown to be false when this condition is assessed by modern diagnostic criteria, and Bedford and Caird's findings support those previously recorded by Kumpe and Bean[2] and Lewes[3]

It is not surprising that the survival-rate was better in the normotensive group than in the hypertensives at all ages in the Oxford survey. What is surprising is the greater number of deaths among hypertensive women, despite the better prognosis of hypertension in women than in men at all ages This difference may be due to the excess of women who die from hypertensive heart-failure in the 70s as demonstrated by Clawson[4] or possibly to a greater incidence of auricular fibrillation in women In normotensive patients the cardiac rhythm did not affect the prognosis; but only 9% of hypertensive subjects with auricular fibrillation survived two years compared with 33% of hypertensives with normal rhythm Bedford and Caird's figure of 6% of patients with congestive failure due to rheumatic disease of the mitral valve indicates the care they took in establishing the diagnosis Rheumatic heart-disease is not rare in the elderly but it may be hard to recognise When at the turn of the century, rheumatic fever and its severe complications were more common than they are today the seriously affected patients were easily recognised, and most of them died before the age of 40 Those with less badly damaged hearts have survived to old age, most of them with mitral incompetence rather than stenosis and nearly half with normal rhythm When symptoms begin late in life often with few physical signs, the underlying condition may readily be overlooked. The prognosis in the rheumatic group, however, is much the same as that of normotensive congestive failure

An analysis of the causes of death is essential to a better estimate of prognosis In Bedford and Caird's series 146 patients died in hospital and 101 were examined post mortem In 33% death was attributed to bronchopneumonia arising either during the episode of congestive failure (8%) or after the heart-failure had resolved and the patient was under treatment for some dissociated condition (25%). Death due to resistant or recurrent attacks of failure accounted for 16% and pulmonary embolism for 14% The figure for embolism may be too low since some of the very sudden deaths were not followed by necropsy and may have included a number of massive pulmonary embolisms Surprisingly cardiac infarction accounted for only 5% but it was included as a cause of death only when the infarction occurred in the last few days of life and when it was confirmed by electrocardiography necropsy, or both Co-existing lethal disease accounted for 7%, and remote causes such as uræmia and cerebrovascular accidents for 14% The high proportion of deaths due to bronchopneumonia is partly a reflection of failure to prevent detect, or treat this condition in elderly patients with congestive failure, and the high death-rate from pulmonary embolism is a challenge yet to be met BEDFORD and CAIRD believe that there is a prima-facie case for giving anticoagulants to all elderly patients in congestive failure, though they admit that many things may complicate the situation and make the treatment unsuccessful It is plain that further experience and knowledge are needed, particularly in the important matter of treatment in the home

Practitioner and Local Authority

“ LET's face it, Clinics Are Unethical ” said RICHARD COBBLEIGH at the end of the brisk exchanges which followed his contribution to the Widdicombe File[1] The correspondence which we published under the title Clinicosis illustrated several different views of the work done in local-authority clinics, but few of those who wrote to us would deny that young COBBLEIGH's remark points to one of the big obstacles to reconciliation between therapeutic and preventive medicine as now practised by general practitioner and local-authority doctor Nor can anyone be entirely satisfied with a system which evokes so many expressions of dissatisfaction the clinic doctor is often aggrieved by the restrictions placed on the treatment he can give at the clinic, the general practitioner argues that the work would more properly and effectively be done by him, and, unhappily, each side sometimes accuses the other of not pulling its weight To all this a satisfactory solution is unlikely to emerge without adoption of some integrating policy Indeed, the uneasy relations between general practitioner and local authority have created such a situation as we had in mind when we referred lately to the need for a return to planning[2]

We welcome therefore a useful step in this direction by the medical officer of health for Staffordshire, Dr GERALD RAMAGE, who has prepared a reasoned analysis[3] of the problem of the general practitioner and the local authority's personal health services He has compared, in an objective way, the views of general practitioners and local-authority doctors on the work they do, and, in the light of these opinions, he discusses the difficulties to be overcome In assessing the value to the community of the local authority's services, RAMAGE refers especially to the defects and illnesses of childhood the clinic workers undoubtedly discover many abnormalities in the children they see, among them conditions that are much the better for early treatment It has often been suggested (by GEORGE et al,[4] for example) that, in child-welfare clinics, the advisory work of the clinic doctors could be taken over by health visitors, and their medical duties by general practitioners But many mothers who take their children to these clinics do so because they know that there they can see and talk to a doctor who is not too busy to give time to comparatively minor troubles, and attendances might fall away if the child-welfare clinics were staffed only by health visitors On the other hand, an increasing number of general practitioners are now running ‘ well-children ” sessions for their own patients, and, as more and more of them are able to do so, the child-welfare clinics will become empty and the health visitors will be free to give more direct help to general practitioners And the same could happen in antenatal and other clinics But it is unlikely to happen for a long time, unless general practitioners are given some financial reward for providing these extra services As things now are, and as RAMAGE's inquiry illustrates, it is doubtful whether the present size of general practitioners' lists allows them time for anything but a gesture at preventive work The figures given in the Cohen report on general practice for the length of the practitioner's working week were higher than those derived from a more recent investigation[5] but what is perhaps more important than hours of work is the practitioner's ability to order his day's affairs around fixed sessions which he can attend with certainty Group practice is the environment that will do most to help him in this way, *and it is in group practice that doctors* may have the ampler accommodation needed for *effective “ clinic ”* work

If the general practitioner becomes able and willing to take on much of the work of the clinics, what changes should be made in consequence in the executive direction of the local-authority services? In the second part of his paper RAMAGE explores the possibilities of control other than by the local health authority, and his comparison between the administrative structure and functions of the executive council and the public-health department is very much in favour of the council For many reasons most general practitioners think poorly of local authority organisations and would be unwilling to serve under them, they dislike an authority which has power to determine the doctor's relationship with his patients, and which gives the doctors it employs so little say in its organisation The proposal to merge the present local-authority services with one of the other existing branches of the National Health Service has been resisted on the grounds that such a union could not cater for school medical services and other special *departments* of the local authority welfare service Alternatively, local authority work might be done by general practitioners if executive-council duties were transferred to the local authority's control, and this, it is said, would make it easier for practitioners to take over the duties of the local-authority doctors, though the plan would be unworkable unless the practitioners were thoroughly satisfied with the arrangements RAMAGE puts forward a programme whereby practitioners could take over by stages the work now being done by clinic doctors and whereby increasing help could be provided for practitioners who run their own clinics Under such a scheme many of the “ public-health doctors ” would ultimately disappear, though there would, of course, always be whole-time posts for other important health-department duties The responsibility of the local authority for the provision of premises could be extended to include a contribution for suitably designed practice premises, and the doctor practising preventive as well as therapeutic medicine should have access to

premises provided for him without paying rent as does the specialist who works in a hospital

Few will dispute RAMAGE s final conclusion—namely that the general practitioner *could* become responsible for the antenatal maternity, infant-welfare, and school branches of the preventive services And if one can judge by the correspondence in our columns most doctors think he *should* do so From this point it could be argued the course is fairly clear more general practitioners must be given the opportunity to prevent as well as treat disease and to take over the work of the clinics and administrative difficulties must be resolutely overcome But there may be complications Under the present arrangements patients can choose whether to seek the advice of their family doctor or that of the clinic doctor for a particular condition and if the family doctor becomes the patient s only source of immediate help there may be dangers in such a monopoly of medical advice Whatever the medical profession may think there is no doubt that many people in this country value the alternative source of advice provided by local-authority clinics, and it would be wrong to disregard this public opinion. If the clinics go the picture of the popular all-embracing family practitioner may be disturbed by an outcry in defence of the clinics, as something the public likes rather than something it still urgently needs Moreover, there may be another administrative formula that would be more acceptable it might be better to separate the personal health services of the local authority from its other duties to the community and transfer them to suitably modified executive councils of the National Health Service This is of course just one of several possibilities (another is the plan proposed by Professor FRASER BROCKINGTON[6] for making the medical officer of health the coördinator of the medical team with general practitioners the first and most important agents in public health) Nevertheless here might be the beginning of an opportunity to link organised preventive medicine with general medical practice at the level where the link would be strongest Doctors health visitors and others now employed by local authorities could be ' seconded to group practices and practice groups, there to work with general practitioners, to teach them and to learn from them In this way " public health might quickly come to have a real meaning in general practice

Treatment of Coarctation of the Aorta

COARCTATION of the aorta should seldom be overlooked if the femoral pulse is sought whenever increased pulsation in the neck brachial hypertension, or unexplained aortic incompetence are detected What is to be done when the diagnosis is made? CAMPBELL and BAYLIS[7] have studied 130 patients with coarctation and they have tried to answer this question by assessing the prognosis In this series 6 patients died who had seemed quite well a year or two before and 4 of them were between twenty and thirty years old Altogether 16 patients died from causes including congestive failure rupture of the aorta bacterial endocarditis and intracranial hæmorrhage all well recognised in this condition[8,9]: and some patients died after operation Symptoms were uncommon in the earlier decades of life though 4 patients had cerebrovascular accidents before the age of twenty, and the blood-pressure after rising sharply until the age of seventeen subsequently remained almost steady Even in the fourth decade the average diastolic pressure did not exceed 110 mm Hg and it is often lower than is generally supposed There was aortic incompetence in nearly a quarter of the cases and stenosis in a further 6 CAMPBELL and BAYLIS regard incompetence as the consequence of bicuspid valves rather than rheumatism and its effects are often slight, with little depression of the diastolic pressure though the incompetence may become more apparent as age advances Absence of symptoms is no guarantee against sudden death and the age of the patients when first seen (only 6 were over thirty-five) suggests a high mortality from the age of twenty onwards For these reasons CAMPBELL and BAYLIS now recommend resection in most children, and they feel it should not be long delayed after eight years Aortic incompetence is an added indication. CRAFOORD[10] and GROSS[11] put the best age for operation at between ten and twenty years because the aorta is then of adequate size and is still free from degenerative changes The mortality of resection was 9% in CAMPBELL and BAYLIS s series and in 648 reported cases they found it to be rather less—7% In CLELAND et al s series[12] of 40 patients who were operated on 3 died including 1 who had a dissecting aneurysm and for whom operation was advised as a desperate resort CLELAND et al suggested that a mortality-rate of less than 10% may now be anticipated in practised hands and the figure is now probably even lower—CAMPBELL and BAYLIS suggest 5% in uncomplicated cases and after GROSS s last 100 operations there were only 2 deaths

After a successful resection, the pressure falls in the arms and rises in the legs but, despite claims to the contrary, COUNIHAN[13] has found that it does not become normal In 20 patients he found that the postoperative pressures remained higher than would have been expected in normal persons of the same age The obvious explanation—that the stricture was incompletely relieved—was rejected by COUNIHAN for a number of reasons The collateral circulation disappeared after operation and the femoral pulse-wave measured by sphygmograms became synchronous with or just preceded that in the radial artery Femoral systolic pressure equalled or exceeded brachial systolic pressure in all except 1 patient, in whom it remained 10 mm lower In 12 cases measurements were made at operation of the aortic diameter at the site of the anastomosis and proximal to it, even when these were identical hypertension persisted. COUNIHAN concluded that the more nearly uniform the aortic calibre after the operation the lower the systolic pressure became—but it always remained above normal WRIGHT et al [14] examined 10 patients soon after operation and again after periods up to seven years In most of them the femoral systolic pressure continued to rise slowly, and to a lesser extent the radial pressure fell As WRIGHT et al put it, ‘ the residual coarctation ” tended to improve slightly during this time, but unlike COUNIHAN’s patients 5 still had femoral systolic pressures significantly lower than brachial pressures after a number of years, and presumably a degree of stricture remained

Why the blood-pressure does not fall to normal is unknown, but nevertheless what fall there is is sufficient to encourage the belief that the complications of coarctation are abolished or much reduced The operative risk is still appreciable, and it is unlikely to improve greatly unless resection is advised before the onset of complications, or before the development of degenerative changes in the wall of the aorta make a difficult operation far more so And even after successful resection, the risk of bacterial endocarditis upon a bicuspid valve remains

Annotations

INFLATION AND BETTERMENT

IF a Government believe that the nation is in critical danger from inflation, and if they are taking difficult and unpopular measures to check it, there is force in their appeal to all sections of the community not to ask for more money Stabilisation of the purchasing-power of the pound would be an advantage for which most of us would be ready to pay a considerable price The policy of our post-war Governments, however, has been directed rather towards slowing inflation than towards stopping it indeed, if unemployment threatens, we may soon see a degree of reinflation permitted This policy may be right or wrong, but if money is to go on declining in value—even if slowly—rational and decent means must be found for adjusting remuneration accordingly

In some countries wages are linked with a cost-of-living index, which alleviates the effects of inflation but also goes far to ensure its continuance In our own country, too, recent responses to wage claims, when not governed wholly by expediency, have been based on this principle Thus we have all read with mixed feelings that administrative and clerical staff earning less than £1200 a year in the National Health Service have been awarded “ a 3% increase in salary on the basis of the rise in the cost of living since February 1, 1956,” [15] while dispensing assistants have had an increase of 5% to allow for the rise since the previous September

In commenting on a similar increase of 3% recommended by the Railways Tribunal “ to match the rise in the cost of living since the last increase,” the *Economist* [16] says that an approximately correct decision has been given for the wrong reasons Wages can be increased each year, without promoting inflation, provided the percentage increase is no more than that of the nation’s real income thus if (as in a good normal year) the national income goes up by about 3%, everybody’s remuneration can go up by 3% without harming the economy This is in line with our own view [17] that the only satisfactory way of financing the National Health Service is that it should be “ accorded, as of right, a defined proportion of each year’s national income ”—of which in turn defined proportions would be used for paying the various groups of people who work in it “ Betterment,” provided the nation continued to prosper, would then be automatic

MOSQUITOES AND MYXOMATOSIS

MYXOMATOSIS was first described in 1898 in Uruguay [1] but not until 1927 was the deliberate infection of wild rabbits suggested as a means of reducing their number in Australia The attempts were only partly successful, apparently because of the absence of insect vectors, for without vectors the disease will spread only when the rabbits are in close contact After the late war further efforts led to the rapid spread of myxomatosis in the Murray valley Investigations into the mechanism of transmission then pointed to the rapid dispersal of infection by the movement of infected mosquitoes, and other vectors in Australia were black flies and stickfast fleas It was thought that the virus did not develop in the mosquito and that transmission was purely mechanical, the insect contaminating its proboscis with virus from the skin lesions of an infected rabbit and transferring it to healthy rabbits up to 25 days later

In Britain, no officially authorised attempt has ever been made to introduce myxomatosis, but when it had spread quickly across Europe in 1953, it reached England (though by what means is not known) and the first case was confirmed at Edenbridge, in Kent, in October, 1953 By the end of 1955 it had reached almost every parish in England, Scotland, and Wales

Late in 1954 an investigation began into the possible insect vectors in this country The rabbit flea is the principal vector, but the activities of mosquitoes were also studied In the part of the country where the first outbreak took place, by far the most prevalent mosquitoes were the woodland aedes, and it seemed reasonable to expect that this common mosquito would find a regular and easily available source of blood in the wild rabbit This possibility was examined by Muirhead Thomson,[2] who showed that, though aedes mosquitoes would feed readily on rabbits in the comatose stage of myxomatosis, they seemed reluctant to feed on healthy wild rabbits By exposing rabbits in cages in woods where the aedes abounded, it was shown that the mosquitoes were not attracted to healthy domestic rabbits which remained uninfected despite months of exposure Though aedes mosquitoes could be infected with virus by feeding on infected rabbits, their unwillingness to feed on healthy rabbits seemed to make them unimportant vectors of the disease

In Australia, anopheles mosquitoes have figured largely in the spread of myxomatosis, and the possible role of *Anopheles atroparvus*, which is the main vector of malaria in Northern Europe, was also considered [3] in Britain It proved to be an extremely efficient vector, capable of carrying the infection through the winter, and, theoretically at least, bridging the gap between the virtual elimination of a rabbit population and the appearance of the healthy progeny of an odd survivor But there is no evidence that anything of this kind does, in fact, happen under natural conditions One possible explanation is that *A atroparvus* rarely bites in the open and lives in dark stables, cowsheds, or piggeries for most of the year But as pigs and stables become fewer, and cowsheds become light and well ventilated, it is becoming increasingly difficult to find this species of mosquito where formerly large numbers would have been expected *A atroparvus* prefers the blood of domestic animals to that of wild rabbits, and Muirhead Thomson concludes that it has little to do with the spread of myxomatosis among wild rabbits in Britain In some places, however, it may help to spread the disease among domestic rabbits. it has been shown that a single bite can infect, and that one mosquito can infect several rabbits in a short time

Though Australian workers believe that spread by mosquitoes is purely a mechanical transfer, Andrewes et al[4] have shown that mosquitoes of this species can remain infective for up to 220 days—much longer than was previously thought The fact that anopheles may remain infective for so long (whereas in the mouthparts of dead mosquitoes the virus survives for only a few days) suggests that there may, in fact, be limited multiplication of the virus But if there is "biological" transmission, it is certainly very different from that of yellow-fever and insect-borne encephalitis viruses

METABOLIC RÔLE OF ZINC

THE belief that zinc is essential to normal development rests in part upon the work of Todd Elvehjem, and Hart,[5] who showed that trace amounts were necessary for the well being of growing rats, but its fundamental importance to all animals became apparent only after Keilin and Mann[6] had demonstrated that the enzyme, carbonic anhydrase, contains 0 33% of the element as an inherent part of the molecule Zinc is now known to have other functions, which have lately been reviewed by Vallee[7]

Of the normal daily intake of 10–15 mg, the greater part is excreted in the fæces, the fraction absorbed maintains a total body store of about 2 g, distributed differentially throughout the tissues In the plasma, zinc (at a concentration of 124 ± 16 µg per 100 ml) is, like calcium, partly bound in non ionisable form to the plasma proteins (about a third is in this form), and partly in loose association with protein in an ionisable form suitable for transport Normal erythrocytes contain 1 44 mg per 100 ml of packed cells, and, at least in health, the slight fluctuations in this figure can be correlated with carbonic anhydrase activity, but no such specific function has been associated with either the protein bound zinc of the serum or the protein-zinc complex which has been isolated from human leucocytes Isotopic zinc (^{65}Zn) is rapidly taken up by the liver kidney, pancreas, and pituitary, but it accumulates more slowly in the bone-marrow and in the circulating red cells High levels are also found in the retina and iris and in the prostate, and it is known that the element can pass across the placenta

Besides its part in the carbonic anhydrase system, there is evidence that zinc, in association with protein, figures prominently in other metabolic changes The zinc isotope which accumulates in the pancreas is secreted in the pancreatic juice and this secretion also contains a highly specific carboxypeptidase enzyme which, like carbonic anhydrase, is inhibited by zinc-binding agents This enzyme has been crystallised as a zinc protein complex, in which the presence of zinc is essential for activity Three other enzymes, alcohol dehydrogenase, glutamic dehydrogenase, and lactic dehydrogenase, each dependent on diphosphopyridine, have also been shown to be zinc-protein complexes

Crystallisation of insulin as a zinc complex has suggested that this element may be an essential part of the active hormone But the experimental evidence does not support this view, for zinc can be replaced here by nickel, cobalt or cadmium, and the amorphous form of insulin which presumably does not contain any metal, has equal physiological activity Yet zinc undoubtedly modifies the action of insulin, since the addition of zinc chloride to insulin before injection delays the action of the hormone Reports of a similar action on gonadotrophin preparations are interesting and justify further investigation

Empirically, it has been found that low serum-zinc levels are often associated with the pyrexia of infection, increased levels are apparently without significance Serum levels are also low in untreated pernicious anæmia, but as there is no corresponding fall in total erythrocyte zinc, the mean corpuscular zinc concentration rises In other anæmias, polycythæmia and leukæmia, the changes in the zinc content of the red cells parallels the hæmatocrit value and the hæmoglobin concentration

Chemical methods for the determination of trace amounts of zinc are not yet as precise as is desirable in work of this kind There is reason to hope, however, that new physical methods including the use of the radioactive isotope ^{65}Zn and the possibility of measurement by flame photometry, may provide a reliable laboratory aid to future advance in this interesting and important field

TOLBUTAMIDE

THE first sulphonylurea to receive a clinical trial in the treatment of diabetes mellitus was carbutamide (B Z 55)[1] The initial German claims that it had a powerful hypoglycæmic action in certain types of diabetes were confirmed, but its limitations also became apparent It was usually of no value in the young patient with severe diabetes, it was definitely contra-indicated in the treatment of diabetic ketosis, and it was ineffective in the presence of complications such as infection Further, carbutamide had a definite action on the bone marrow in a certain proportion of cases, and a special warning was issued about this danger[2] Other less serious side effects included skin rashes and interference with thyroid function

The second sulphonylurea to be investigated was tolbutamide, which has a methyl group in place of the *p* amino group of carbutamide, and many reports have now appeared[3] There are certain differences in pharmacological properties between carbutamide and tolbutamide The hypoglycæmic effect persists, though tolbutamide is slightly less active,[4] but the bacteriostatic action is lost[5] Of greater importance is the question of bone marrow toxicity, and this is always more difficult to assess The dangers of carbutamide in this respect were not fully appreciated until some time after its introduction The evidence so far suggests that tolbutamide is considerably less dangerous than carbutamide, though it is not entirely innocuous since it too may produce leucopenia[6] Both substances suppress the uptake of radio iodine, but tolbutamide is less active in this respect[7–12] Clinically this side effect has not so far been important, but clearly this anti thyroid action must be borne in mind if lengthy treatment is needed Skin rashes are occasional complications with both carbutamide and tolbutamide [12,13]

The hypoglycæmic action of the two drugs apparently depends on the same principle [14], and there is no evidence that a diabetic patient who does not respond to one compound will react favourably to the other The way these substances produce hypoglycæmia is still uncertain, and the position has not been greatly clarified since we commented [1] on this subject six months ago

There are certain characteristic differences between the actions of insulin and sulphonylurea in producing hypoglycæmia Insulin increases the glycogen content of muscle, unlike sulphonylurea, which, on the other hand, increases hepatic glycogen [15,16] It is thought that the sulphonylureas may act by decreasing the release of glucose from the liver [7,17], but this view is not universally accepted These compounds are ineffective after total pancreatectomy, but small doses have a definite hypoglycæmic action when injected into a pancreatic artery No effect on the blood sugar level follows injection into the portal vein [18] Other evidence points to the fact that they can act only in the presence of some functioning pancreatic tissue and supports the view that tolbutamide has a direct action on the islets of Langerhans [19]

The persisting uncertainty about both the mechanism of action and the hazards of long continued administration means that the use of tolbutamide should be restricted to carefully planned therapeutic trials Its widespread use, even in the type of diabetes that might respond, is certainly unwise Many of the patients who might respond are overweight and can often best be treated by dietetic measures alone In more severe cases the attraction of treatment by mouth should not outweigh the fact that insulin is still the physiological replacement

PESTS AND PESTICIDES

MANY chemical substances used to control insect pests and plant weeds are toxic to man and other mammals, and the widespread use of these substances is an occupational hazard to sprayers and factory workers There is also a potential danger to the general population from food which may contain minute amounts of these substances, applied at some stage during its growth, preparation, or preservation These problems have been recognised by many governments, and the views of an international panel of experts, set up under the auspices of the World Health Organisation, have lately been published [20] Chemically, the pesticides fall into two large groups the chlorinated hydrocarbons, which include dicophane (D D T), chlordane, dieldrin, and endrin, and the organophosphorus compounds, of which parathion, T E P P, malathion, and chlorthion are examples The mechanism and the symptoms of poisoning are quite different in the two groups, but the fundamental actions of individual members of each group are similar

Those who are anxious to have the most effective materials they can get must also ensure that these can be used with safety to both man and animals Clearly, information on the toxicity, safe methods of use, and the treatment of poisoning must be readily available before effective field programmes can be planned Animal experiments provide basic information on comparative toxicity But the methods of applying an insecticide in different environments may result in unexpected poisoning Thus, dieldrin poisoning has been troublesome among workers in Venezuela, where it is used to control the vector of Chagas's disease, but dieldrin has been used in Africa and Indonesia for malaria control with no untoward effects For several reasons, the difficulties of getting up to date information, and therefore of controlling adequately the use of insecticides, have become greater during the past few years An increase in the number of insect species attacked and the development of resistance by the insects have led to an increase in both the quantity and variety of chemicals used In 1946 resistance was reported in only 1 species of insect, but by 1956, 34 species were known to be resistant to these insecticides—a change which emphasises the need for laboratory investigation and careful field studies before making recommendations about the use of such substances

The clinical signs of early poisoning by either the organophosphorus or hydrocarbon compounds are not specific The late signs of poisoning by organophosphorus compounds are due to the accumulation of acetylcholine at nerve ganglia and motor end-plates of muscles—muscle fasciculation, bronchospasm, abdominal pain, terminal convulsions, and coma In serious poisoning by the chlorinated hydrocarbons, there is incoordination of movement, irritability, with intermittent clonic tonic convulsions, and finally respiratory failure Specific tests can establish the diagnosis of poisoning by the organophosphorus compounds (depression of the blood cholinesterase activity is a characteristic action of this group) But no satisfactory laboratory test has yet been devised for detecting poisoning by any of the chlorinated hydrocarbons, except dicophane In dicophane poisoning, dichlorophenylacetic acid (D D A) is excreted in the urine

The routine animal experiments which are carried out before any new substance is recommended as a pesticide may also throw light on the mode of action of the new compound It is often found, however, that laboratory animals show considerable species differences in their susceptibility The W H O report recommends that greater emphasis be given to studies of human beings who have been exposed to pesticides, and the report also devotes many pages to the discussion of measures for the protection of operators handling pesticides Points of particular importance are that the workmen should be made fully aware of the risks involved, and if men exposed to organophosphorus compounds are found to have a low blood-cholinesterase level, further exposure must be forbidden even though no symptoms or signs of illness are apparent

Though the amounts of pesticides present in milk flour, meat, fats, and water are insufficient to produce symptoms of acute or chronic poisoning, no one knows what damage may follow the continued absorption of small amounts over long periods For this reason volatile chemicals should be used as far as possible and the amount applied should be kept down to a minimum It is known that dicophane, dieldrin, and gammabenzene hexachloride are eliminated in the milk of lactating animals, and dicophane has been found in human milk For this reason, these substances should not be used as insecticides in dairies or be added to cattle feeding stuff. Another consideration is the effect on domestic animal and fish—for example, when applying insecticides for the control of malaria or molluscicides for the control of bilharziasis, the concentration of insecticide in the water must be well below the level which would harm the fish The W H O study group decided that no recommendations could yet be made about the maximum safe limits for residues of pesticides on food, because of the shortage of reliable information

INDIVIDUAL REACTIONS TO CHANGE
AS SEEN IN SENIOR MANAGEMENT IN INDUSTRY*

ALEXANDER KENNEDY
M D Lond , F R C P

PROFESSOR OF PSYCHOLOGICAL MEDICINE,
UNIVERSITY OF EDINBURGH

In these days the idea is current that the greater part of nervous breakdown is due to intimate rather than external causes But many psychiatrists are now coming to believe that stress related to the simple business of living and working may be of at least equal importance And of the breakdowns which occur, a great number are directly related to a failure to adapt successfully to change or the need for change For this reason management is a most promising field for mental hygiene

Man, we learn *from the Koran,* is incapable of perfection , and in its low level of accuracy and large number of errors human performance compares ill with that of most forms of machinery This, however, is the price we pay for two qualities in which the human organism far excels any machine of its creation—namely, *complexity* and the capacity for *self-regulation and profiting from experience* In man alone there have developed from these qualities such attributes as initiative foresight, responsibility and appreciation of human relationships But unfortunately these attributes which are essential for leadership in any major enterprise remain scarce, and they are very unevenly distributed That their correlation with intelligence in the academic sense is relatively low explains many of the mistakes in personnel selection

Like man industry must adapt to changing conditions Within its organisation it will have a considerable division of labour, and, in terms of cybernetics, will include regulators, discriminators predictors, and integrators, linked to a certain number of generalisers It is the generalisers that are *responsible,* ultimately, for the direction of change , and the future of industry depends on their selection, training and distribution, in place and time, and on maintaining the fickle flame of their efficiency—for they are only human

One of the trends in business organisation is the increase in the proportion of administrative to operational staff If twenty men drawing only moderate salaries and working at half pressure could be as effective as ten men working at full pressure, this might not matter so much, but it is not so If they can be obtained a smaller number of men earning more pay and doing much more work in the same time will produce far better results

INSECURITY

It is with the causes of inefficiency in the components of the regulating mechanism—the senior managers and directors—that I shall now deal

If I have any complaint of boards of directors or groups of senior executives it is that they are far too considerate when one of their number falls into my hands Their consideration often takes the form of concern lest he should lose his job and the dignity and authority that go with it They will bemoan the pace of modern industry, and if given the opportunity, they will furtively *compare* the patient s case with their own These men have recognised that it may be their turn next The strain of doing a job for which they are no longer fit, their determination to hang on to what they have got, is written all over them They are insecure In my view their value as generalisers is often limited, for they share with the neurotic the urge to save their own skins If the generaliser is no longer able to identify his own aims with those of the firm in an enlightened self-interest, if he is preoccupied with holding on to his personal status and the *status quo,* this attitude will extend to his work and he will albeit unconsciously, resist change

Most people in industry are well adjusted preserve a good balance between their industrial and private lives and generate no unhealthy inward tension so that if their task is well designed for them and if it is one that gives an opportunity to make use of their abilities, attitudes and interests, they will work at maximum efficiency In their case modification of their work may create a temporary but healthy tension which has the function of keeping them alert during the period of adaptation In those who are less well adjusted however, even the suggestion of change and the threat of being called upon to do or to understand something beyond their abilities brings the threat of breakdown They are unable *consciously* to accept the reasons for their uneasy feeling about the new idea and rationalise their position and convince themselves that all change is perilous and all chance unsound " Their response is not always clearly evident They may in fact appear very enthusiastic until the implications of the proposed change in terms of personal reorientation have sunk in The delayed change of heart after a day or two is a known characteristic of this group

Among those in senior positions in an organisation the tendency to hold on to power as such is apt to increase as real capacity diminishes Use is frequently made by the insecure of the fact that the man who is trying to get a new idea across has to use many times as much energy as the man who wishes merely to obstruct him passively The sense of power through refusal learnt in the cradle is experienced again with new and ego-sustaining satisfaction

Where resistance to change is of emotional rather than rational origin the ways of overcoming it may *sometimes* have to be oblique in the extreme If one is to be a bringer of change and progress, a good deal of time has to be spent *on just this process for* a cause will rarely sell itself entirely on its own merits Means must constantly be found for providing spiritual gain for those who are to support it

MATURITY AND INERTIA

Only a small proportion of humanity has the capacity the energy, and the wish to act as generalisers Yet many find themselves either thrust into this position or are there *by* a passive operation of promotion The human brain in the most intelligent *groups* is not *mature* until the age of 25, at which time there is still much more to be learnt But after 25 there is a very slow decline in the speed *of thought* and the capacity for learning Between 25 and 35 the seeds of a man s best ideas are laid down even if they flourish much later After 35 maturity and experience must compensate for the gradual but definite slowing of mental activity which is *taking place* A few, with sound brains and well-trained habits of mind, can maintain their originality well into the senium, but in one whose ability has never been adequate, or whose decline has been more rapid than usual, the mental mechanisms by which he keeps up with his work and conceals the truth from himself and others are fully in operation by 40 The most powerful weapons protecting him are *tradition* and *promotion by seniority* Too often the advice which should be given to a firm is " It would be economical to pension this man off generously—to pay him to stay away " But by that time of life the currency acceptable to him is not so much cash as prestige

---

* From an address to members of the Duke of Edinburgh's study conference on the Human Problems of Industrial Communities within the Commonwealth and Empire, July 14 1956

It is unfortunately not yet possible to get spare parts for the human machine, and the brain in particular can lose components but never replace them Nor can one easily scrap the machine and find a new one at once, for it takes time to train a senior manager for the particular needs of the organisation he is to control I should not like to give the impression that I always consider the more change the better, or think that continual change is necessarily healthy On the contrary, the formation and maintenance of stable routines is an essential But it is evidence of high morale in a human group that there is no mental set against the possibility of change, that new thought can be generated without having to overcome too much inertia of mind and that the capacity to adapt to change has not been lost In the same way continual changes of staff as well as methods may have an adverse effect on morale There seems, however, to be nothing whatever to be said for inbreeding at the top end of management, and the practice of introducing chairmen and heads of departments from outside must surely keep managers in competitive trim If a firm, through such a policy, tends to lose personnel because they cannot feel secure, the loss in experience may be made up by a gain in initiative

THE RESPONSE TO STRESS

Breakdown occurs in both the successful and the unsuccessful, and in that the former adapt better to change, their outlook is usually better In fact some very successful men with a very sure touch in their business affairs require in their private lives to be propped up by psychiatrists, astrologers, diets, and wives, and this is clearly worth doing

A feature of some successful executives is the intermittency of their drive They will accomplish a great deal in a few short weeks, after which they are less in evidence until another quantum of energy is available It is characteristic of them that they respond to change, even when they have not themselves initiated it, with a burst of energy Their moods are often quite predictable to their secretaries, though not to themselves This intermittency is consistent with a high intellect and is a liability which those gifted with the ingredients of success must often accept Few are able to live through an active progress to senior positions without showing some signs of strain, but these are usually self-limiting

Inability to adapt to one's circumstances creates a sense of inadequacy, of inward tension and insecurity This tension, which may be brought about by many other kinds of psychological stress, is the common basis of neurotic breakdown Where a person can face his own inadequacy—be he ugly, clumsy, stupid, or merely lacking in drive—and change his circumstances, even at the loss of prestige or pay, so that he can cope with them, he will not break down Perhaps I should say, *would* not break down, for I have yet to meet him One and all, we are bolstered up by self-deceptions and comforting ideas which we are not in the habit of examining very carefully

Some causes of tension in managers are

(1) *Sudden change to a task requiring rapid and complex adaptation in a man who has been too well organised for too long*

(2) Failure to accept with resignation a position inconsistent with ambitions

(3) Decline of ability to keep up with a job which is too responsible and calls for more initiative than can be found without strain

(4) Conflict between identification with firm's interests and competing interests at home

(5) A degree of intermittency in drive which has allowed the individual to take on more when "high" than he can cope with when "low"

(6) The cumulative effects of a type of drive which makes delegation difficult and prevents a reasonable relationship of work to leisure

(7) Increasing uneasiness at the prospect of retirement for which no mental preparations have been made

The tension generated shows itself in various ways, all of which have an indirect effect on efficiency

(1) Poor sleep, bad temper, continual grumbling, longer hours of work but less achieved Symptoms usually attributed to overwork

(2) Repeated minor sickness Consulting specialists and self medication, often accompanied by an interest in life assurance and financial security

(3) Procrastination Working from in tray to out-tray and losing sight of long term aims Working by the clock rather than by the interest of the job

(4) Feeling of frustration and persecution by colleagues. Complaints of lack of cooperation

(5) Increase in alcoholic intake and verbal output Technical jargon and catch phrases replace original thought

There is a tendency to underrate the importance of alcohol as a contributory cause in breakdown at the senior levels It provides a readily available and socially acceptable escape from the sense of insecurity, and the premium put on extraversion and interpersonal relations in business predisposes to its use in excess There might be some question whether firms are getting their money's worth out of the bonhomie generated by their expenditure under this heading

BETTER SELECTION AND ALTERNATIVE PLACEMENT

How is it possible to bring into the regulating mechanism of a firm a sufficient proportion of people who are capable of exercising foresight and of applying it in the form of change ? Also to get them into this position while in their prime and to get them out of it before the onset of the *defensive decline* described above, if they are not capable of keeping up the pace Two possibilities at least are worth considering—*better selection,* and *alternative placement* for those whose initiative is waning

Managers capable of going to the top are scarce Probably, in the immediate future a lower proportion will come from the universities, for these are at present saddled with an excess of expert examinees, intellectually precocious but immature in character, who have had (in relation to their contemporaries) their peak performance in the years between the "eleven plus" and the General Certificate of Education It is fortunate that industry is offering opportunities to those who have failed to get into universities and who have reached maturity on the job There are also the sons of middle class parents who (because of taxation or the means test for educational grants) cannot be sent to the university but can be accepted for training in industry from the outset Again, the technical and research branches of industry can contribute a large quota to senior management A firm which can take ten possibles, and, having given them all special opportunities for rapid training, can produce one first class manager, is not making a bad bargain if three more can find satisfactory places lower down in the pyramid

Though they are fallible and have caused disappointment, selection methods can help Applied psychology is still inclined to lay too much stress on brightness as opposed to other less measurable qualities It is apt, too, to be excessively preoccupied with the exclusion of those who may actually break down as opposed to those who will merely be inefficient and who in fact are far more expensive in the end But that some organised selection is better than none is now being realised by those firms who are getting the left-overs from those who do select Selection does not have to be 100% successful to be a good investment

The selection of the future administrator is a continuous process, and while a promising entrant is learning his job he must be frequently re assessed, for there is no method of selection as reliable as the long-term observation of the individual's reaction to a succession of real situations There is no reason why it should not be recognised as continuing throughout his career in industry

Senior managerial staff who are unable to maintain initiative may be valuable in a position in which they can use their experience In the larger organisations it should be possible to have a staff structure designed so that those who have a chance to go on to the very top should not be as well paid as those who, having got so far in the general administration, may prefer to take a more specialised post with higher pay, earlier retirement, and as high sounding a title as is considered possible The way to the top would thus be hard, with the option at any time of compromising for the more specialised but more lucrative post with less influence on general policy

There remains the problem of the inadequate but ambitious, the dogs in the administrative manger Experiments with methods by which members of a group of seniors make an annual report, without consultation, on the fitness of each of their colleagues, are of great interest in this country, because when a Briton is asked to pass judgment of this kind he usually will do his best to be objective and will not at once seek to form a voting bloc The results of such experiments, carried out with due care for secrecy and anonymity, indicate that the method might be useful if it became the established custom to ask for assessments of this kind and to correlate them statistically over a period of years While it remains the custom to " carry " those who have become drunken, idle or prematurely incompetent the cost will remain high Financial security is desirable as age advances, but to assure personal prestige as well as material security is more than the economy can bear

From the point of view of one whose news of the battles of industry is mainly derived from the casualties left on the field, it appears that the ideal of management is a body of individuals who see their own advancement, and the satisfaction of their personal drive, in pursuing the aims of their organisation, who are conscious of the responsibility of recruiting young men to their number on a basis of merit alone, and who have an established system of using the experience of those who can no longer stand the pace of change As the pace of competitive industry accelerates there can be no room for traditional self-deceptions, and direction must surely be placed in the hands of those who can not only accept but will welcome change

CLUBS FOR " MIXED " HANDICAPS

MOST of the voluntary organisations for the disabled have been formed to help people with a particular handicap or disease Thus there are societies which look after the welfare of spastics, of people with poliomyelitis, or of the blind The St Raphael Clubs are unusual in that they are open to nearly all handicapped people, from teenagers to old-age pensioners, regardless of their disability

The first club was started ten years ago by the parents of some handicapped children in Norwich The name was chosen because the angel Raphael was sent to help the sons of Noah in their adversity Ten clubs have now been set up, including those at Hexham, Romford, King's Lynn, Colchester, Swaffham, Lowestoft, and Wayland, a rural area of Norfolk

The clubs offer recreation and social help to handicapped people The limitations of disability are lessened by the fun and satisfaction of doing things (however small) together, and of meeting old friends and making new contacts—not always an easy thing for the disabled Companionship underlies everything done in every St Raphael club A one ailment club can breed an odd sort of preoccupation But at a St Raphael club the patient with poliomyelitis, for instance, is shown the problems and courage of spastics, arthritics, and the blind

The clubs are run as much as possible by the members themselves, but much of the work is of course done by the least handicapped and by able bodied supporters Surgeons, almoners, and occupational therapists help with their special knowledge, organisations such as the Red Cross, the Churches, and the W V S help in many ways, and transport is provided by Rotary and Round Tables

The Norwich club has a membership of 110 and an average attendance of 75 at its weekly meetings It has its own premises, a small redundant school which was bought a few years ago after great efforts by the members and their supporters There is a large hall, now complete with piano and stacking chairs, a small lounge with easy chairs and a television set (given by the local Round Table), a room with a billiard-table and workshop tools, and a kitchen Other organisations of handicapped people, such as the Invalid Tricycle Association, are allowed to use the rooms when free On Saturdays the club is open from 3 P M until after 9 P M Older members hold their weekly meetings on a different day from the younger generation Entertainments vary from film shows and outings to concerts and short plays A small choir leads a monthly religious service held by members and their friends Some members make and sell toys, and for the past two years the club has held a competition and exhibition of handicrafts, to which the other St Raphael clubs have contributed It has also found jobs in offices for several members, and a local firm has provided piece work to be done at the club itself

The Hexham and Wayland clubs serve country areas, and their membership is less than 50 But the need they meet is perhaps even greater than in larger towns Thus the Hexham club includes blind people, who in Norwich, where the numbers are larger, have an organisation of their own

Each club is recognised by the authorities for the receipt of grants Members pay 6*d* per meeting—held weekly in Norwich, monthly in the smaller clubs For blind members there are special grants

Public Health

Nursing-homes in London

THE report for 1955 of the medical officer of health for the county of London [1] includes an account, by the late Dr E B Argles, of nursing-homes in the county Whereas in 1937 170 nursing-homes were registered the number had fallen to 108 in 1945, 63 in 1947, and 48 in 1953 Rising costs, says the report, have alarmed the users as well as the owners of nursing-homes Accommodation which before the late war cost 5–8 guineas a week today costs 11–25 guineas, but this is not a disproportionate increase when compared with rises in costs

Confinements in nursing-homes numbered 1001 in 1952 compared with 3107 in 1947 This large drop is not due wholly to the fall in birth-rate from 20 9 per 1000 population in 1947 to 15 3 per 1000 in 1952 Most homes have found that in the post-war years less use has been made of their operating theatres, whereas more beds are being used for medical cases and particularly for the treatment of chronic sick or senile patients " Establishments which provide care for the aged by ordinary unskilled staff fill a real need, and there are good reasons why some of the smaller nursing homes should turn their attention to this type of elderly person who so often fails to find the accommodation for which he or she is seeking "

Before Our Time

"DOCTOR"

GEORGE GRAHAM
M A, M D Camb, F R C P
CONSULTING PHYSICIAN TO ST BARTHOLOMEW'S HOSPITAL, LONDON

THE word "doctor" has no less than twelve different meanings, but only two of these concern medical men[1]—a degree in a university and the name given to a medical practitioner

As a degree it was first used in the medical school of Salerno[2] about the middle of the 11th century It was next used in the law school of the University of Bologna[2] in the middle of the 12th century as a degree superior to that of magister, and soon afterwards it was introduced at Paris,[3] first in the divinity school and later for law and medicine Oxford University,[3] which was founded about 1167, gave a doctorate in divinity, and sometime in the 13th century one in law and medicine Cambridge University,[4] which was founded about 1209, also gave a degree of doctor in these subjects Until the University of Durham was founded in 1832 these were the only two universities in England which could grant the degree of doctor in physic, but the other universities in the British Isles—St Andrews (founded in 1411), Glasgow (1451), Aberdeen (1494), Dublin (1591), Edinburgh (1583)—all gave degrees in medicine

At the present time Oxford confers the degree of doctor in seven faculties An estimate of the respective numbers in each faculty, obtained from the University Calendar, is divinity, 99, civil law, 31, medicine, 234, letters, 58, science, 68, music, 29, philosophy, 883 The total of these figures (1402) is probably on the low side, since if the doctor removes his name from the "books" it is omitted from the calendar But it will be seen that of some 1400 who have a doctor's degree and can call themselves Doctor, fewer than 250 are doctors of medicine

Outside the universities, degrees in divinity, civil law, and medicine were formerly conferred in this country by the Pope After Henry VIII assumed the post of "Supreme Head of the church and clergy as far as the law of Christ will allow" (Act, 25 Henry VIII, c 21) in 1534, these powers were transferred to the Archbishop of Canterbury, and the degrees are now called the Lambeth doctorates[5] Thomas Cranmer did not confer any degrees in medicine, but, of the 451 Lambeth degrees given between 1663 and 1848, 31 were in medicine and 13 of the recipients do not seem to have had a medical qualification The last degree in medicine was conferred in 1880[6]

The other common use of the word is for a medical practitioner, and its first recorded use is by Langland[1] Chaucer used it in 1386, saying "With us ther was a Doctour of Phisyk"[7] The older word for a medical practitioner was a leech, and this is noticed as early as the year 900[1] Chaucer said in 1386 "What nedeth hym that hath a parfit leche To sechen other leches in the toun"[1,8] Both words seem to have been used in the succeeding centuries, but in the 17th "leech" was applied to veterinary practitioners

* * *

When the Royal College of Physicians was founded in 1518, its fellows and licentiates did not call themselves Doctor unless they had the degree of doctor of medicine in either Oxford or Cambridge or one of the universities in the British Isles

Surgeons about this date in London were members either of the Barbers Company, which contained both barbers and surgeons, or of the Guild of Surgeons which was less influential and poorer than the Barbers Company[9] These two united in 1540 when Henry VIII granted a charter to them as the Barber Surgeons Company[9] The members of the company rarely if ever had the degree of doctor of medicine and did not call themselves Doctor The Surgeons separated from the Barber Surgeons Company in 1745 and formed their own company This was dissolved in 1796 and a royal charter was granted to the new College of Surgeons in 1800 During the 360 years since the foundation of the Barber Surgeons Company, few surgeons would have had the degree of doctor of medicine, and surgeons would not have been addressed as Doctor

The rise of the apothecary began to cause difficulties in the profession An Act of Parliament in 1815 gave the Society of Apothecaries the right to appoint a court of examiners to examine all apothecaries to ascertain the skill and abilities of such persons in the science and practice of medicine and their fitness to practice as an apothecary Further, in 1827 the society asked for proofs of training in midwifery which neither of the Royal Colleges demanded, so that the holder of the diploma of L S A might have had a better all round qualification than the licentiate of the Royal College of Physicians or the member of the Royal College of Surgeons Between the years 1815 and 1883 no fewer than 31,000 men were licensed to practise by the Society of Apothecaries and it was thought that five sixths of the London students in 1822 were studying for general practice as surgeon apothecaries[10] Many of these men, who were not licentiates of the Royal College of Physicians, called themselves Doctor, and this custom caused a good deal of ill feeling, especially when the Medical Act was passed in 1858 This Act required, among other things, that all should register their qualifications with the General Medical Council *The Lancet*, the *British Medical Journal*, and the *Medical Times* of 1860 contain many letters complaining that licentiates of the Society of Apothecaries called themselves Doctor whereas those of the Royal College of Physicians were not allowed to do so—which made the general public tend to regard the licentiate of the Society of Apothecaries (L S A) as superior to the licentiate of the Royal College

The matter was brought to a head when an action was brought against Hubert Edward Kelly, who lived in Pinner, because, although he had registered only the qualifications of M R C S, L S A, he styled himself Doctor The action was dismissed by the magistrate and was heard on appeal in the Court of Exchequer before the Lord Chief Baron and two other barons The Lord Chief Baron, in dismissing the appeal, said "If a man is registered, he may call himself what he pleases," and "the Act (Medical Act of 1858) is to prevent any man practising medicine who is not registered"[11] This case was complicated by Kelly having produced documents which showed that he had the degree of Erlangen University, and, though he had not registered this degree, he was clearly entitled to call himself Doctor

The Royal College of Physicians paid no attention to this decision, and in 1862 published its by law in English which said

"No Fellow, Member, or Licentiate of the College shall assume the title of Doctor of Medicine or use any other designation, name title, or distinction implying that he is a Graduate in Medicine of a University, unless he be a Graduate in Medicine of a University"[12]

There the matter rested until after 1884 when the two Royal Colleges agreed to set up a Conjoint Board to conduct the examinations in medicine, surgery, and midwifery under conditions which satisfied the requirements of the General Medical Council and to grant a Conjoint diploma[13] Having done this, the two colleges considered whether they could not grant a degree instead of only a diploma Their proposal was rejected in 1889 by the Royal Commission upon the Higher Education in London[14] Two years later a proposal to delegate "pass degrees" to a joint board, nominated partly by the senate of London University and partly by the two Royal Colleges, was rejected by convocation[15] Three years later the two colleges approved a plan to found a second university in London to be called the Gresham University, which would have been a teaching university independent of London University[16] This scheme was eventually rejected by a Royal Commission in 1900 when a new constitution was granted to London University The two colleges were each given two representatives on the senate, and under the constitution "powers were granted to the Senate to make arrangements to conduct jointly with the Senate examinations in such portions of the subjects in the course of study for a medical degree as may be agreed upon between the Senate and those Colleges" (Statute 123)[17] This statute has never been acted on, and after careful consideration in 1903[18] and again in 1910 and 1911,[19] the Royal College of Physicians "decided that it was inadvisable that the College should take any further steps to promote the scheme of a Conjoint Examination contained in the report dated 1910" This ended the efforts of the twenty-six years on the part of the two colleges to grant degrees to their licentiates and members

In 1905 the secretary of the Royal College of Surgeons wrote to the Royal College of Physicians saying that his college received many complaints from its members about the by-law forbidding them to use the title of Doctor, and hoping that the Royal College of Physicians might see its way to withdraw its prohibition[20] The matter was carefully considered by the Royal College of Physicians but in April 1906, the comitia decided by a large majority to make no change in its by-law[21] However in July, 1911, the comitia again considered the matter because of more complaints by its licentiates and because of the impossibility of preventing licentiates from using the title of Doctor if they defied the college As a result the by-law was amended in 1912[22] and now reads

> "No Fellow, Member or Licentiate of the College shall append to his name the title of Doctor of Medicine or the letters M D or any other letters indicating that he is a Graduate of a University, unless he has obtained a degree entitling him to do so"

The meaning of the by-law may be summarised in the words which the Chief Baron used in 1860 "If a man is registered he may call himself what he pleases" At the time the by-law was passed the whole medical profession and its press was deeply concerned with the struggle over the Lloyd George National Insurance Act and *The Lancet* did not comment on it until nearly five months later[23] The concluding sentence of its annotation runs

> "Previously the distinction between practitioners who did or did not hold University degrees was rather an invidious one as it tended to the idea that their professional skill and knowledge were similarly unequal, which was by no means necessarily the case now without fear of any reproach for using a forbidden term, the Licentiates of the Royal College of Physicians and the Members of the Royal College of Surgeons can adopt the professional title which is generally understood by the public to indicate that they are duly qualified practitioners of medicine"

* * *

Now that forty-four years have elapsed since the by-law was altered, the general practitioners all call themselves, or are called by their patients, Doctor, whether they have the degree of doctor of medicine or not The newly qualified house officers are treated in a very unequal fashion In some teaching hospitals both the house-physician and house surgeon are called Mister In others the house-physician is called Doctor and the house-surgeon Mister In the great majority of non-teaching hospitals, I understand that, both are called Doctor, though in some the house-surgeon is called Mister Although the Royal College of Surgeons had striven so hard to get the by-law altered so that its members might be called Doctor, its fellows and those of the sister college of Edinburgh refuse to be called Doctor and insist on being called Mister, as though that were a superior degree

This curious practice which does not exist in any other country (so far as I know), except in those Dominions of the British Commonwealth which follow the practice of the Royal College of Surgeons, seems to arise from the old antagonism between the Royal College of Physicians and the Barber Surgeons Company after its formation in 1540 The members of the company rarely if ever had a degree of doctor of medicine, and their general education was certainly inferior to that of the physicians. Further, judging by the rules which William Harvey, in 1633, laid down for them at St Bartholomew's Hospital they were under the domination of the physicians[24] Nowadays, when the general education and qualifying examinations are perforce the same for both physicians and surgeons, it seems peculiar that the distinction should still exist, and that the surgeons should still seek to preserve the insignia of their inferiority in the Middle Ages This practice seemed most peculiar when an elderly anæsthetist (now dead), who had always been styled Doctor, was elected a fellow of the Royal College of Surgeons and insisted on being addressed as Mister The fellows of the Royal College of Obstetricians and Gynæcologists, and all who aspire to become Members of that College, also refuse to be called Doctor and seem to glory in being called Mister This is more difficult to understand seeing that fifty years ago they all called themselves Doctor The custom seems to have started about the time of the foundation of the college and it is difficult for an elderly physician, who is proud to call himself Doctor, to understand why the change was made

The practice causes a good deal of confusion among patients and the general public who cannot understand why a properly qualified doctor should not be so called It also causes some inconvenience to themselves if they travel in countries where all medical men are called Doctor Is it too much to hope that one day everyone who has a registrable qualification will be called Doctor and that this curious survival will cease ?

I have to thank the Registrar, Sir Harold Boldero for permission to consult the Annals of the Royal College of Physicians of London and Mr L M Payne, F.L.A., for his great assistance in searching the records

In England Now

A Running Commentary by Peripatetic Correspondents

THROUGH hell and high water we uphold the cause of Freedom In our mountain fastness we are quite used to swinging our little motor cars around the hairpin bends and down the 1 in 4 gradient that leads to the village We do not clutter up the valley with warning signs and suchlike cossetting Our cats' eyes blink contentedly by the hearth, our white lines stay by the dartboard We have the room and the time to enjoy the pattern of sunlight on the fells, to swerve round the sheep in the road, to stop for a chat on the corner We would be thought plain daft if we waggled our arms about with fancy signals as it says in the *Highway Code* Likely cause a nasty accident

The well-meaning efforts of the old grannies on the councils of other areas fire us with proud contempt We hoot with derision at their steep-hill triangles on a simple 1 in 8, we shriek drovers' oaths at the sight of their cattle-crossing signs, we sail airborne over their silly little humped-back bridges So it was when we set out with a tank full of basic ration to return our heir to school Convention demands that out of a pile of dubbined rugger boots, squash racquets, tuck, electrical gadgets, and general haberdashery, all duly numbered and name-taped, we should emerge in decent habit to pay our respects to the Housemaster before abandoning the offspring

We always try to grant the last wishes of the condemned, so that was why we took the coast road Tide-tables mean even less to our valley than road-signs We greeted with growing hilarity a succession of boards which told us that the road was impassable at high-water, that duck-shooting was strictly reserved, and that bathing was dangerous We pressed on in the usual way towards the wheeling seagulls At the edge of the saltings we ran slap into a sheet of water, but, as it was only a few inches deep, I whistled a cheery hornpipe and surged on round the bend The bow wave was piling up, and so was my better half's anxiety The heir, of course, was delighted Then with a strangled splutter the exhaust sank below the surface and we hove to A quick glance at the daily paper predicted a 31 feet tide with high-water in another half-hour By the way the sea was sluicing across the road it was doing its best to comply through the floorboards

The heir and I ripped off our shoes and socks, rolled up our Sunday-best trousers, and stepped out into an ice-cold January flood My wife bundled up her fur coat and high heels to sit cross-legged at the wheel while we pushed our mock amphibian towards the distant shore Some unfeeling engineer had tar-sprayed the road with granite chippings, so sharp that they penetrated even the stocking anæsthesia of the freezing waves But Fate was kind once we had done our penance Henry Ford's hardy product shook itself and spat seaweed out of the silencer We wrung the water out of our pants and arrived in the quadrangle looking more like the end of term than the start We dumped the body and drove away like mad Of course the brakes would not work, but apart from that minor distraction we kept a vigilant eye on the road-signs all the way home The price of Freedom without doubt

* * *

Into the middle of a dull surgery came Mary, all smiles and looking very well She sat down and said " A've given o'er wark " Wondering what was coming next I gave a non-committal "Yes," and she continued "and a've brought this for thee," holding out a pound note Still nonplussed, I asked her why I should have it and she explained that she had just come from the post-office and this was half of her first retirement pension " Dost thou not remember ? " she said

And then indeed I did Mary's winter coughs were always accompanied by some degree of asthma, but about twelve years ago she had a particularly resistant wheeze and she became very despondent She thought that her time had come and that she would never get back to work again "I shall never live to draw me pension, and think of all them stamps a've bin puttin' on for all these years," she moaned. To cheer her up I suggested that we should make a bargain If I kept her alive until she could draw her pension we should share it between us—fifty-fifty I had forgotten, but she had remembered and here was her thank-offering " It's for thee," she said, " to give to any charity that thou likes "

There are still a lot of nice folk about

* * *

A very clearly marked feature in many neurotics is an inability to make decisions This can be elegantly demonstrated by the coal-cellar test

The patient is ordered to fill a coal scuttle in a well lit cellar He cannot decide which lump is the most suitable to put in the scuttle, and characteristic pawing movements are observed A viewing window of one way glass is a convenience The test is now repeated in total darkness Since the lumps cannot be seen, there is no hesitation as to which to reach for, and the performance may be greatly speeded up

The ratio of time-in-the-light to time-in-the dark is taken, and a value greater than unity indicates neurosis Resentment will increase filling-time, but since this is likely to be felt more keenly in the dark than in the light, a time-ratio greater than unity will always be significant

* * *

Outside our front gate a small dog came abruptly into contact with a small car from which an even smaller man sadly emerged We watched as its last few breaths were quickly spent in the gutter " Daddy," asked Jo (aged 3) " Did that doggie run across the road and bump into that man's car and get bleeded ? " " Yes," said Bill (5), " and now he will go to a hospital and be made all better like Daddy does Daddy, will you make him all better ? " " What a silly doggie," concluded Jo, deep in thought " Oh, no," explained Bill " It's not his fault, his Mummy and Daddy should have stopped him, shouldn't they, Daddy ? " " Daddy," said the youngest, giving me no chance to get in, "what will they do to that doggie ? " At last I had the opportunity of explaining that my hospital didn't take dogs, and, anyway, he was beyond my skill " Well, what will they do with him ? " There was no escape " I expect they will take him away and bury him " " Oh, but that's unkind," said Bill at once That was lost on me, and I sought enlightenment He explained " Because that will make him even more dead " Quite defeated, I went for help to the kitchen " But that's a very sensible remark," said my wife, and returned to the washing up

The psychological damage from this incident does not seem to be as deep as I had feared Over the bath later that week I was asked à propos of absolutely nothing " Daddy, when I'm as old as you are, how old will you be ? " *Rapid calculations on the wall led me to con*clude " 51 " (28 minus 5 plus 28 I think) " And when I'm 51, how old will you be ? " (Deep thought) " 74 " " And when I'm 74, how old will you be ? " (More deep thought How Much Longer O Lord ?) " 97 " " And when I'm 97 how old will you be ? " Seeing no end to this, and in an admittedly unguarded moment " I shall probably be dead " No damage, however, this was greeted with uproarious laughter and much jumping about " And when you're 97 how old shall I be ? " he ended up " You'll probably be dead, too," I said Enormous amusement at this, both of them quite incapably convulsed with mirth

What about it, Sigmund ?

In Wales family connection used to be shown by placing the word " ap " (the son of) before a name, and traces of this remain in Parry, Pugh, and Pritchard, sons of Harry, Hugh, and Richard When this method was discredited, the English " son " took its place, but after the name, and John's son and Hugh's son became Jones and Hughes But the remote valleys tended to become over populated with one family and it became necessary to invent a method of naming the subspecies as it were so the occupational system was evolved—Mr Thomas the Post or Hughes the Milk Sometimes, however, the nicknames have a more topical basis In our village Owen John Williams is an auctioneer and is known as Owen John the Going Gone, while Thomas Jones, who has only two central incisors left, one up and one down, is Thomas Jones Central 'Eating

Letters to the Editor

HYPERTENSION: PRESYMPTOMATIC DIAGNOSIS AND TREATMENT

SIR,—Formerly it was held that hypertensive patients become accustomed to their high blood-pressure, which is then necessary to maintain the circulation. Even today many authorities say that hypertension should not be reduced unless it is causing symptoms.[1–3]

But we are in an era when the emphasis is on early diagnosis and early treatment and it is hard to see why hypertension should alone be left untreated until it reaches a stage when nothing much can be done about it. In most cases of hypertension the rise in blood-pressure at first is transitory, labile, and asymptomatic. Why then should we not try to detect it at an early stage and keep the blood-pressure down by comparatively simple measures? Surely we should look on hypertension as a reversible illness, which, like an attack of asthma, should be brought under control as quickly as possible, though we cannot guarantee that it will not recur. We are not unduly nervous about telling a patient that he is suffering from tuberculosis, valvular heart-disease, or diabetes. Why then should we continue to teach that it is best not to tell the hypertensive patient that his blood-pressure is raised? I agree that the actual blood-pressure readings should not be mentioned; but I believe that the patient should certainly be told that he has a mild elevation of blood pressure, that he should follow certain simple restrictions on his activity and diet, and take some drugs for a time.

On the principle that high blood-pressure, like other disorders, should be treated as soon as it is discovered, I am at present studying a series of eleven cases, of which the following is representative.

In February, 1955, Dr A, aged 51, complained of headache with a tired feeling at the end of the day. The only abnormality found was a blood pressure (B.P.) of 168/106 mm. Hg. The B.P. recorded 4 months earlier had been 130/84. Though there were no other symptoms or complications I decided to treat him with comparatively mild hypotensive agents. He was given reserpine 0·25 mg. twice a day, and 'Theogardenal' (phenobarbitone and theobromine) one tablet twice a day, and advised to reduce his sodium intake by half. The B.P. was recorded on alternate days and in 2 weeks it fell to 140/90. The dose of reserpine was reduced to 0·1 mg. twice a day and stopped after another 2 weeks. The blood-pressure has since remained about 140/90.

The other ten patients have all had a diastolic pressure persisting above 100 mm. Hg for several weeks, and have been treated on the same lines. All have responded, though one showed a recurrence after 4 months and another after 7 months. These episodes of recurrence yielded to similar treatment. In only one case pentolinium tablets had to be used to bring the pressure down initially, the milder hypotensives not having acted.

Of the eleven patients, three were women and eight men, their ages ranging from 42 to 56. They have been under observation for periods varying from 4 to 21 months.

The classification of essential hypertension into benign and malignant is completely misleading. It should be given up. The term "benign" can properly be applied to a condition which has hardly ever been known to cause death, but hardly to essential hypertension in which about 90% of the patients die sooner or later of the well-known complications. For too long this totally inappropriate terminology has led physicians to ignore the presence of hypertension and adopt an attitude of expectancy with folded hands until complications set in, by which time it is practically impossible to reverse the changes. With a diastolic pressure fixed at about 130 mm. Hg, the measures required are more complex and more doubtful in their results, and there is the additional danger that thrombotic complications may be precipitated by over-zealous treatment.

The idea that once a mild hypertensive is started on a regime of dietetic control and drug therapy he is likely to require these for many years, is probably incorrect. A large series of cases should be studied the world over to obtain data regarding the late results of early treatment of asymptomatic hypertension. In such studies workers in India can play as large a part as those in the West. Of the many fallacies surrounding essential hypertension, perhaps the most serious as that there is no hypertension in the rice-eating peoples of the East or that hypertension is a disease of Occidental civilisation. Physicians who have worked in India know that high blood-pressure is exceedingly common in India both in the cities and in the countryside.

THE PLIGHT OF HOSPITAL PHARMACY

SIR,—As chairman of the committee that examined some aspects of hospital pharmacy for the Central Health Services Council a few years ago, I must thank you for your timely survey of its staffing problems (Jan. 19).

You rightly identify inadequate salary scales as a main cause of the shortage of hospital pharmacists, and there is no doubt that there will be no significant increase in recruits until salaries improve. But in pharmacy, as in other sections of the health service, that is by no means the whole story. In some respects the problem is akin to that faced by general practitioners. They are asking for higher remuneration, but over and above that they look for better conditions of practice. Dissatisfaction does not show itself so obviously among general practitioners because for them the alternative to grinning and bearing it is a major operation such as emigration to Canada. For pharmacists there is the simpler alternative of moving into one of the other branches of pharmacy, and that is what they are doing. Like the general practitioner, the hospital pharmacist looks for a professional career that is progressive and satisfying as much as financially rewarding, and too many hospitals fail to provide it.

A campaign to increase recruitment cannot succeed if it is linked only with better salaries. It will be necessary for management committees to consider in consultation with their chief pharmacist how far the inadequacies of their pharmacy departments may be responsible for shortage of staff. Many of them need substantial replanning. A large number of them were never properly designed when the hospital was first built and have been left for years to grow haphazardly. Moreover, it should go without saying—but often does not—that the chief pharmacist has the authority and responsibility which must be accorded to the head of a department if he is to do full justice to his work. He must have the effective voice in the purchase of his materials and engagement of his staff. He should be able to report direct to the management committee and to attend its meeting when pharmaceutical affairs are discussed. One of his chief duties should be to tender advice to the medical staff about prescribing efficiently and economically, and he should have access to the medical committee for that purpose.

The salary scale for pharmacists should depend more upon the complication of the work in their department than on the size of the hospital. It should bring a pharmacist up to a good competence at forty or so and beyond that there should be a sufficient number of well-paid senior posts throughout the service to attract good men to a hospital career As you emphasise, special rewards for higher qualifications are likewise important for this purpose More pharmacists can be recruited into hospitals only when it is generally understood by those in authority that the present staff shortages are due to a general neglect of the hospital pharmaceutical service, which is slowly running down because no-one is tackling the fundamental defects The service can be rebuilt, but only if it is given a new deal and a new look in all its aspects

PRESCRIPTIONS FOR DIABETICS

SIR,—The medical subcommittee of the British Diabetic Association has now clarified with the Ministry of Health some financial alleviations for diabetic patients on the new prescription regulations

To be brief, a Ministry letter of Nov 27, 1956, states that the supplies of needles, spirit, testing tablets, and —most important—insulin can be prescribed for three months or more depending on the doctor's view in the individual case One shilling only per item would be payable, irrespective of the quantity ordered

HYPOPITUITARISM AND GONADAL DYSGENESIS

SIR,—I feel sure that many of your readers who, like myself, are not experts in the pathology and biochemistry of the hormone deficiency diseases, would welcome some reassurance about the paper by Dr Jackson and Dr Hoffenberg in your issue of Dec 15

This describes the case of an old man who was admitted to hospital for treatment of hepatomegaly and piles The authors state that he was suffering from dwarfism, mental deficiency, epilepsy, severe anæmia, and considerable œdema of the legs and sacrum They explain how cretinism was suspected and go on to describe an insulin tolerance test which resulted in hypoglycæmic coma and death

One must presume that the insulin tolerance test was used in preference to the exhibition of thyroid because of some advantage such as greater safety or greater certainty of the result, which might be reflected in greater certainty of treatment, and hence, greater advantage to the patient Unfortunately this point is not made clear in the article

One would also be interested to know whether the patient was held to have died accidentally, as the result of an accidentally produced hypoglycæmic coma, or whether the death was held to be due to a pre existing condition

I ask these questions because the authors themselves make it clear that the patient was incapable of coöperation (and therefore incapable of giving consent to an experiment), because the photograph (fig 1 in the paper) seems to indicate considerable distress on the part of the patient (however, the photograph may well be misleading) and because the article makes no reference to the efforts which must have been made to alleviate the patient's condition

In cases of this kind, where the scientific interest is great and the end result to the patient of little scientific importance, it is only too easy to give the false impression that the scientific interest is the only one involved, I feel sure that the authors would welcome an opportunity to correct this impression in this case

London, N 1
R E W FISHER

*** We have shown this letter to the authors of the article Their reply follows —ED L

SIR,—We should like to assure your correspondent that the humane aspects of this case were not overlooked, but that only the basic scientific facts were given in the published report Actually at the time of investigation of this case (1952) we were quite unaware of its great scientific interest, which became apparent to us later while studying problems of sexual differentiation We stress that the investigation referred to was *not* purely academic, but was pertinent to the handling of the case

Shortly before seeing this patient we had investigated two cases of adult cretinism, and we felt fairly sure that we were dealing with another one An insulin tolerance test was considered valuable to rule out the possibility of hypopituitarism which we (mistakenly) felt was very unlikely At the time it was considered dangerous to exhibit thyroid alone in hypopituitary cases, so that this investigation was undertaken as a routine One of us was present during the insulin test and administered intravenous glucose as soon as possible after the coma, which rapidly restored the blood sugar but the patient remained unconscious and was found to be hypothermic He died two days later, having never fully recovered consciousness, despite our best attempts at resuscitation Hypopituitary patients are well known to be subject to such a mode of death He did not die in hypoglycæmic coma, although we readily admit and deplore the fact that this episode appeared to have started the train of events which led to his death, which, however, could not have long been delayed in any case

Regarding the photograph, the patient was weak and unable to stand without assistance His appearance of distress is easily explained by his efforts, which were required for only as long as it took to work the camera shutter

We openly acknowledged our error of judgment in this case, but we really hope that we have vindicated our ethical integrity

R HOFFENBERG

DANGEROUS CONTAMINANTS IN STORED BLOOD

SIR,—I am greatly relieved that Dr Drummond (Jan 12) thinks that experts can sample blood bottles with a very low contamination rate I wish he could persuade the authors of *Notes on Transfusion*, issued by the Ministry of Health, that this is true, for that booklet makes it mandatory to mark as "Dangerous for Patients" every blood bottle 24 hours after it has been sampled Some regional transfusion directors refuse to accept this directive, and insist that blood must be used even when more than 24 hours have elapsed after the bottle has been entered[1] I am glad that Dr Drummond thinks (as indeed I do) that this practice is safe, but it is to my mind scandalous that any regional transfusion director should enforce the use of a bottle of blood which, according to the Ministry's advisers, is dangerous for patients—the more so since, if the patient died, the pathologist would have the greatest difficulty in justifying the action forced on him by the regional transfusion officer

There seems to be no general agreement on how deaths associated with transfusion should be classified I submit that one should discriminate between deaths due solely to transfusion and those associated with disease treated by transfusion For example, during a transfusion given very rapidly because of torrential hæmorrhage the citrate anticoagulant might lower the ionised calcium level enough to cause heart failure, the ensuing death should not be ascribed to the transfusion I think this difference will explain the difference between the frequency of transfusion deaths accepted by Dr Aidin and myself Deaths due solely to transfusion can be classified into (*a*) hæmolytic reactions due to serological incompatibility, stale blood, or blood damaged by heating or freezing, (*b*) bacterial contamination, (*c*) cause unknown

Bacterial contamination itself is often of no importance, for the entry of a few bacteria at the time of administration is harmless, as is shown by the excellent results obtained by the open method The problem is different with stored blood, for, though pathogens hardly grow at

---

[1] *Lancet*, 1955, i, 205

+4°C, some saprophytes do so with generation times of the same order as that found by Dr McEntegart (Nov 3)—and also with the lag period he found. Such bacteria cannot kill by colonising the patient, but may do so by causing a reaction to their own body proteins or to their metabolites, and they may kill in this way even if they themselves have first been killed so that Dr Marsh's (Jan 12) criteria for deciding whether death was due to bacterial contamination are not valid. It does follow, however, that blood contaminated with a few saprophytes is dangerous only after the bacteria have had a chance to multiply, and Dr McEntegart thinks that this period of relative harmlessness may be as long as 14 days. If this be so, I cannot see any rationale for doing stained films on all blood bottles which are to be issued.

In this hospital, if the patient becomes ill after transfusion, the transfused blood is cultured at 20°C and at 37°C—and so far out of some 25,000 bottles no reactions attributable to bacteria have been encountered. Can Dr Aidin (Dec 22) or Dr Stark Murray (Jan 19) tell us how many patients have been saved from contaminated blood by their stained film procedure? Or, for that matter, can anybody else who has been working in England during the last ten years? *Experientia docebit*

GEORGE DISCOMBE

A MISSED FRACTURE

SIR,—I read with considerable misgiving the report under this heading (Jan 19).

Firstly, the coroner has no power to criticise anyone; his job is to determine the cause of death and nothing more. Such criticism should be disputed on the spot, for it may well be quoted in subsequent claims for damages.

In this particular case one should not be too sure that the casualty officer failed in his duty. He was sent an old lady with an injury to her arm, he dealt with this and returned her to the care of her own doctor. It is admittedly to be regretted that he did not diagnose the fractured femur, but neither did he find a fractured skull, diabetes mellitus, and a host of other possibilities. If a casualty officer, or any doctor, thoroughly examined and investigated every patient he saw, he would never leave his surgery or consulting room.

The final sentence is even more ominous. The public has a right to be treated—and nothing more. It has no right to expect "completeness," and in particular no right to be cured—as many seem to think.

Newcastle General
Hospital

Senior casualty officer (surgical)

HYPOTHERMIA

SIR,—I wonder whether the initiators of artificial hibernation know about their predecessor who practised this therapy (though in a primitive form) during the 1914–18 war. The information comes from one no less than Mahatma Gandhi,[1] who was suffering at that time from severe dysentery.

> "Whilst I lay thus ever expectant of death, Dr Tadwalker came one day with a strange person of Maharashtra. He is not known to fame, but the moment I saw him I found that he was a crank like myself. He had come to try his treatment on me. He had almost finished his course of studies in the Grant Medical College at Bombay without taking the degree. Later I came to know that he was a member of the Brahmo Samaj. Sjt Kelkar, for that is his name, is a man of an independent and obstinate temperament. He swears by the ice treatment which he wanted to try on me. We gave him the name of 'Ice Doctor.' He is quite confident that he has discovered certain things which have escaped qualified doctors. It is a pity both for him and me that he has not been able to infect me with his faith in his system. I believe in his system up to a certain point, but I am afraid he has been hasty in arriving at certain conclusions. But whatever may be the merits of his discoveries, I allowed him to experiment on my body. I did not mind his external treatment. It consisted in the application of ice all over the body. Though I am unable to endorse the effect that he claims his treatment had on me, it certainly infused in me a new hope, and the mind naturally reacted on the body. I began to have an appetite and to take a gentle walk for five or ten minutes."

The event took place whilst "the deadly war in Europe was still going on."

A NEW CLINICAL ENTITY?

SIR,—The epidemic of aseptic meningitis which has been observed in different parts of England,[1–4] and which seems to involve pronounced pleocytosis in the cerebrospinal fluid (C S F)[5] has also been prevalent in different countries on the Continent.

Between June and November last year innumerable cases of aseptic meningitis, sometimes with exanthem, were reported in Belgium. The manifestations were roughly the same as those so described by your correspondents.

1 Definite meningeal symptoms, with or without the now well known rubella-like exanthem, fever, headache, back and neck stiffness, severe muscle pains, vomiting, photophobia, sometimes conjunctivitis, and, characteristically, a very pronounced pleocytosis with cell counts ranging from 50 to more than 3000 cells per c mm. Recovery was the rule, but there was a notable tendency to relapse.

2 A kind of "summer influenza fever," sometimes accompanied by rash, in which no meningeal symptoms were clinically obvious, though lumbar puncture sometimes revealed C S F involvement.

As was pointed out in this journal,[6] there was no "striking evidence of involvement of the substance of the brain and cord", but mixed infections with poliomyelitis virus were recorded in Belgium, and proved by laboratory findings.

This disease seemed to be very easily transmissible and we know of many multiple family or secondary cases, as described by Dr Pickles[2] and Dr Lyle.[3] Between July and November we isolated 156 virus strains—122 from stools, 28 from C S F, and 6 from throat. These viruses were cytopathogenic for monkey-kidney cells but not for HeLa cells. That all these viruses were of the same strain can be presumed from the results of cross neutralisation tests: any virus isolated was neutralised by any patient's convalescent serum, as well as by rabbit serum after immunisation with one strain chosen as reference.

The identity of these similar strains was evidenced by the following tests: no neutralisation occurred, either by monkey anti-poliomyelitis sera, or by those standard rabbit anti-E C H O virus sera (received from Dr A Sabin) which corresponded to types 7, 8, 10, 11, or by rabbit anti-E C H O virus sera, ranging from type 1 to type 14 (9 excepted). However, indubitable neutralisation was always observed with anti-E C H O-9 serum.

Inversely, among standard E C H O viruses received from Dr A Svedmyr and Dr J L Melnick, ranging from type 1 to 14, type 9 only was neutralised by patients' sera, and by rabbit antisera corresponding to Belgian strains.

79 of the patients showed the same rise of neutralising antibodies, between acute and convalescent sera, towards Belgian virus strains and towards E C H O virus 9.

---

2 Pickles W N *Ibid* p 1047
3 Lyle, W H *Ibid* p 1042,
4 *Ibid* p 947
5 *Ibid* 1956 i, 789
6 *Ibid*, 1956, ii 1091

Neutralisation results seemed to be confirmed by complement-fixation tests

The same outbreak of aseptic meningitis was also observed in the Netherlands[7,8] and in Switzerland[9], from a Swiss stool specimen we have isolated an ECHO-9 virus, and one strain received from the Netherlands[7] proved to be also of type 9

Dr F Dekking, of Amsterdam,[8] has also typed several strains as ECHO 9 and has found them to cause myositis in suckling mice At the beginning of this epidemic we inoculated suckling mice with different stool specimens, without ever provoking clinical symptoms Possibly pathogenicity for suckling mice is enhanced by several passages on tissue cultures, so we are now going to proceed to new inoculations of suckling mice with tissue-culture passaged strains as inoculum Anyway, the Belgian reference strain was not neutralised by Dr G Dalldorf's standard anti-Coxsackie sera, corresponding to the types A1–17 and A19 and to types B1–5

Whatever antigenic or clinical correlation may be found later on between Coxsackie and ECHO groups, we feel justified meanwhile, in suggesting that the aetiological agent of the Belgian outbreak of aseptic meningitis was a single strain of virus, antigenically identical with the American ECHO-9 standard virus strain

Considering the epidemiological and clinical similarities, one may be tempted to wonder whether the same agent was not responsible for both the British and the Continental outbreaks of aseptic meningitis

Such aseptic meningitis caused by ECHO viruses have already been described by several workers[10–14] Mainly prevalent in the U S A are types 4 and 6[13 15 16] Other types of ECHO viruses have been found associated with some rather isolated cases of aseptic meningitis[13 14 17] Moreover, Neva and Enders[12] isolated in 1954 an agent, afterwards identified as ECHO 6,[18] during an outbreak of exanthem without meningitis in Boston

University of Ghent EMILE NIHOUL
Institut Pasteur Brussels LISE QUERSIN-THIRY

SIR,—With reference to the series of articles and letters that has appeared—under various names—since last May, it may be of interest to record that we described a similar outbreak that occurred in two villages of the Meon Valley in 1948[19]

There was a total of 29 cases, 8 of whom were admitted to hospital between Sept 23 and Oct 27 The outstanding symptoms were moderate pyrexia, severe frontal headache, vomiting, and pain and stiffness in the back of the neck

A positive Kernig's sign was a fairly constant feature The pyrexia subsided with the disappearance of symptoms in a few days Of the patients treated in hospital, 4 exhibited a transient rash, 5 complained of photophobia and 2 had severe insomnia

The cerebrospinal fluid showed an increased cell count in all cases investigated, but there was no paresis at any stage Virus investigation yielded negative results

S CHALMERS PARRY
Winchester ROBERT A GOOD

PLEURAL BIOPSY

SIR,—Closed pleural biopsy, to which you refer (Jan 19), is likely to prove a safe and useful diagnostic procedure Through the kindness of Mr Abrams and Mr J W Jackson, of Harefield Hospital, I have used a needle which allows of aspiration of fluid and biopsy of the parietal pleura in one operation I hope to report a number of such biopsies later The following case is an example

A young airman was admitted with erythema nodosum and a pleural effusion The composition of the fluid was compatible with underlying tuberculosis, no organisms were found microscopically Biopsy of the parietal pleura showed granulation tissue, highly suggestive of tuberculosis A diagnosis was thus established within a few days

I am grateful to Dr Drew Thomson and Dr A C Pollard, of the Middlesex Hospital, for the histological report

Royal Air Force Hospital,

Wiltshire P MESTITZ

PSYCHOTHERAPY IN GENERAL PRACTICE

SIR,—Dr Neville Davis's letter of Jan 19 was read with particular interest by the group of four general practitioners at Darbishire House Health Centre where for the past eighteen months Miss Madge Dongray, a trained social worker, has been giving full time assistance with some of the medicosocial problems arising in day-to-day practice Since for all of us this was a new experiment in collaboration, it may be useful to describe how we set about it

It was agreed at the outset to refer to the social worker problems which worried or puzzled the doctors and in which her specialised knowledge and experience[1] might prove helpful This method differed from that of Dr Davis and Mr Heimler in that we did not specially select problems of "mental health" but left each doctor to decide for himself where he felt the need of help

Many of the problems thus referred were practical difficulties—concerned, for example, with the care of the aged, employment, housing, and finance—in which help could be given to the doctor and the patient in using the social services more effectively At the end of ten months, however, we found that in just over half the cases discussed between doctor and social worker the most significant factor was directly connected with mental and emotional health This group of 72 cases was roughly classified as

1	Psychiatric illness with suspected psychotic features	13
2	Severe neurosis	6
3	Chronic anxiety state	4
4	Less severe anxiety or depression as a more or less persistent factor	5
5	Sudden emotional crises (either at recurrent intervals or in reaction to special circumstances)	14
6	Behaviour problems in children	11
7	Mental deficiency	4
8	Gross marital dysharmony of long standing	5
9	Problem families	10

Many of these cases presented somatic symptoms such as headache, palpitations, and vomiting, although we are not sure whether they could be correctly classified as "psychosomatic"

Dr Davis's experiment in three corner consultation gives food for thought At our centre, where the patient is introduced to the social worker by the doctor, much thought has been given to the way in which the doctor should propose this consultation to the patient, and also to the content of the social worker's interviews with the patient and of her discussions with the doctors either individually or as a group We are learning to understand the importance of feeling—both in the patient and in ourselves—and to examine how our own attitudes, expectations, and anxieties influence the extent to which

[1] Miss Dongray formerly worked as a hospital almoner and in 1952 completed a year of study and practical work under supervision in the child guidance department of the Tavistock Clinic, London

we can help the patient One of us at least admits to a considerable increase in tolerance since the experiment began

Although at present the "listening" function may be left too often with the social worker, the fact that the doctor has to decide when and how to refer tends to increase his awareness of the emotional content of his interviews as well as of the significance of the patient's social background the fact that, in many cases which were previously baffling, real help can be given makes careful and generous listening worth while

Like Dr Davis, we have found that many patients are substantially relieved by one interview, while some need more and a few have been taken on by the social worker for long-term assistance Others need referral to a psychiatrist or to the child guidance clinic or other special sources of help, but there is evidence that the nature of the initial interviews plays an important part in determining whether he can make good use of this specialist aid The wisdom of interviewing relatives and generally understanding family tensions which affect the patient's health has also been evident

Unlike Dr Davis and Mr Heimler, we have attempted work in which children are involved, because we feel this is extremely important for prevention and because it is the particular interest of the social worker Interviews with parents of children often result in an easing of tension, with benefit to the child We have a further line of defence in the psychiatrists attached to the family-welfare service and the child-guidance clinic, who give generously of their time in discussing cases where it is not strictly necessary to refer the patient for psychiatric consultation or child guidance but where the doctor and social worker need advice and support

Medical students spending a fortnight of their final year with the practitioners are also taking part in case-conferences with the doctor and social worker, at which our method of working is demonstrated and debated.

We, too, feel that "the journey is just begun"

HENRY W ASHWORTH
HUGH DAVIE
H GOLDIE
J LENTEN
MADGE DONGRAY

Darbishire House Health Centre,
Manchester

SIR,—Your leading article of Dec 29 and the subsequent correspondence have far greater implications than might at first be evident

Dr Davis has described how, working with relatively simple techniques, we helped some 70% of the patients in our series to make a partial or apparently satisfactory adjustment to their environment In 1955 I reported[1] on 41 people, seen at the request of the National Assistance Board, who had been drawing National Assistance for at least two years, and of whom 20 returned to work The method used, in essence the same as that practised in conjunction with Dr Davis, rehabilitated many patients who otherwise might still be "on the dole" Likewise from the economic standpoint it may be worth mentioning Dr Davis's impression that the amount of drugs prescribed for the patients we studied was considerably less than that prescribed for similar patients who were not included in the experiment

From every point of view it seems desirable that all who deal with the emotionally disturbed—including not only doctors but officers of the National Assistance Board and Ministry of Labour officials—should appreciate the importance of recognising persons who may derive benefit from this type of work As such recognition would produce a demand for help for far greater numbers than at present, I personally believe that everybody dealing with people in this category should have some guidance in interpersonal relationships, and especially in recognition and appreciation of their own emotional responses, as Dr Davis has brought out in his letter This may be utopian, but a beginning must be made somewhere

London, N 12

EUGENE HEIMLER

TREATMENT OF SORE THROAT

SIR,—In the three letters from general practitioners last week, I was glad to find general agreement on the general practitioner's authority to speak on sore throat But two of your correspondents attribute to me opinions which were not voiced in my letter of Jan 19

I did not state that all cases of sore throat should be treated with penicillin On the contrary I went to some lengths to distinguish tonsillitis from pharyngitis, and advocated the universal use of penicillin therapy only for tonsillitis The common cold is often accompanied by sore throat, which may be the presenting symptom, but this is quite different from the acute inflammation accompanying tonsillar infection, which is also distinguished by cervical adenitis and pyrexia Tonsillitis is often unilateral—an indication of its separate entity and distinguishing it from the general inflammation accompanying catarrhal infections Hence my plea for discrimination, on clinical grounds alone, when deciding whether or not to use antibacterial drugs in this condition

I think that the paper by Chapple et al[1] effectively answers Dr Fry's plea for a demonstration that oral penicillin shortens the course of acute sore throats This paper is an excellent example of the usefulness of such practical investigations in general practice

It is hardly surprising that I have not met a nasty stomatitis caused by penicillin lozenges, since I never employ this utterly useless form of medication When referring to oral penicillin therapy in my letter I was careful to qualify this with the word "swallowed" I fear that this must have escaped Flying Officer Smith's notice, since there was no reference to penicillin lozenges in my letter I am surprised that he should resurrect the old bogy of induced penicillin resistance The hæmolytic streptococcus is remarkably immune to this phenomenon, and, even after ten years' widespread use of penicillin, iatrically induced drug resistance is virtually confined to our hospital wards If this was due to inadequate dosage, our hospital staffs would have much *to answer for!*

Twickenham

DAVID WHEATLEY

SERUM-LIPIDS AND ATHEROSCLEROSIS

SIR,—The ætiological and therapeutic problems of atherosclerosis are so admirably dealt with in two articles in your issue of Jan 19, that it seems almost improper to criticise them It is, however, a sad comment on our times that the "references" are so numerous but, nevertheless, so defective By this I mean that only papers in the English and American languages are mentioned, though much valuable work has been published in Europe, particularly in Germany It is surprising that neither the name Schettler[2] nor the work of Küchmeister et al[3] receives mention Both these groups have reviewed the subject in much detail, and have called attention to the value of certain lecithins (from soybean) and 2 4-5 polyoxyethylene sorbitol mono oleate in causing atherogenic serum to become normal Of course, it is not certain that such a state of affairs implies that the atherosclerotic process is being prevented or improved, but there is no doubt that the preparation mentioned exerts the type of action claimed by these authors It appears that the constituents exert an indirect effect on the cholesterol/phospholipid ratio, causing it to approach the normal 1 0 certainly the serum changes that follow administration of the preparation cannot be due simply to the small amounts of lecithins, &c

London, W 1 A PINEY

SARCOIDOSIS

SIR,—We are glad to have Dr Consden's criticism (Jan 12) of our paper on bacterial residues in sarcoidosis[1] and would like to make further observations on the points he raised

We have stained by the Ziehl Neelsen method extracts of normal human skin, subcutaneous tissue, brain, liver, lung, kidney, heart, and skeletal muscle, and subcutaneous rheumatoid nodules, as well as several chemicals such as oleic and stearic acids and cholesterol When decolorised with acid alcohol (10% HCl in alcohol) none of these was acid fast In this we do not agree with Dr Consden We find that when decolorisation is completed in two stages in a carefully controlled manner, as suggested by Philpot and Wells,[2] and as mentioned in our original paper,[1] using 25% sulphuric acid followed by alcohol, these substances are not acid fast We would suggest that each stage of decolorisation should be for at least half an hour

On the other hand, the extracts of the four cases of sarcoid were each strongly acid and alcohol fast and resisted decolorisation with 25% H_2SO_4 followed by alcohol for a period of 24 hours in each stage

Dr Consden states that, if mycolic acid were present, it would certainly form only a very small proportion of the total fatty acids We do not know the source of this information as we are not aware of published work besides ours which deals with the fatty acids found in sarcoid lesions It should be borne in mind that the fatty-acid content of sarcoid lesions may bear no resemblance to that of normal tissue or to that of tubercle bacilli and that we dealt with tissue that in no way histologically resembled normal

The more important findings were that the extract from each case of sarcoid was shown to be, on infra red spectrophotometry, a long chain fatty acid Each spectrum closely resembled the published spectra of mycolic acid[3,4] Randall et al[5] claimed that each fraction of the extracts of tubercle bacilli is identifiable by spectrophotometry In our original article[1] the spectra had only one absorption band in the region 1180–1320 cm^{-1} In fatty acids containing up to 21 carbon atoms, there are many bands forming a progression in this region[6] This evidence rules out the possibility of fatty acids of up to 21 carbon atoms

Each sarcoid extract isolated had a melting point in the range 54–58°C (the melting point of mycolic acid is 54–59°C[7–9]) and was a white powder

In two of the lesions studied (lung and cervical gland) we had sufficient material to extract these tissues after pulverisation, according to the classical methods of Anderson and other workers[4, 9–11] Using these methods, most if not all other closely related substances associated with mycolic acid, such as palmitic, oleic, stearic, and phthioic acids, are removed during the fractional separation We were left in each case with a white powder, whose melting point and spectrum were similar to those of mycolic acid

Taking all these facts into consideration it would seem to us justifiable to regard this organic substance as mycolic acid, as it is a white powder at room-temperature, has a melting-point between 54 and 58°C, is isolated by classical methods from tissues by a method that separates closely associated substances from it, is strongly acid-fast, and above all has the spectrum of a long-chain fatty acid that is extremely similar to mycolic acid

We would emphasise again that these positive results have been obtained on only the four examples of "sarcoid" that we have examined, and we are anxious to obtain more material for investigation

W G STRAWBRIDGE
Cardiff S E NETHERCOTT

SIR,—The studies by Mr Nethercott and Dr Strawbridge on the chemical composition of sarcoid nodules are interesting and suggestive, but the authors presume a degree of specificity for their findings which may not be justified

Contrary to their statement, a lipid of the mycolic acid type with the same infra red spectrum has been described as a normal component of the human body[1] It seemed then, as it does now, that tuberculoid reactions and the chemical extractions for mycolic acid have the same level of only partial specificity Where there is a tuberculoid granuloma, there should be a compound resembling mycolic acid, but if such a compound can come from such diverse cells as spermatozoa and mycobacteria, it conceivably can have yet a third source in sarcoidosis

Department of Pathology,
Memorial Center,
New York JOHN W BERG

RECURRENT MOTOR PARALYSIS

SIR,—The interesting case described by Dr Breen and Dr Emond in your last issue suggests a possible diagnosis of myasthenia gravis Admittedly, the disorder is rarely seen before the age of 10 years, but I have met with cases between 4 and 7 years, and examples are described for example, by F R Ford at 5 and 6 years and even younger[2] The manifestations of myasthenia in children are often atypical, but facial paralysis is not infrequent and involvement of the diaphragm is known to occur If and when the symptoms reappear, a neostigmine test should confirm or disprove myasthenia gravis

London, W 1. C WORSTER DROUGHT

DILUTION OF INULIN

SIR,—When, some time ago, I became interested in the study of renal function, I turned in vain to the available literature to determine the correct diluent and dilution for 10% inulin to render it isotonic for intravenous or subcutaneous administration

As supplied by Messrs Kerfoot, pyrogen free 10% inulin is a supersaturated solution in distilled water that requires dilution for constant infusion if the solution is to remain stable without recrystallisation during the course of an experiment

Using serial dilutions of the 10% inulin solution in distilled water, and heparinised washed human red cells as an "*osmometer*," I found that the undiluted 10% inulin solution was isotonic with human red corpuscles, there was an increase in the packed cell volume of the red cells with a dilution of 7 5%, and hæmolysis became visible when dilutions of 5% or higher were used

This indicates that the 10% solution of inulin as supplied may be used undiluted shortly after dissolution by heating for priming doses, but should be diluted with 0 9% sodium-chloride solution for sustaining infusions I have found it convenient to calculate the amount of 10% inulin necessary per minute to sustain a plasma level of 40 mg per 100 ml, and to make up this to 1 ml per minute with isotonic saline solution

I hope that these results will be of value to any two confronted with the same problem as was I

MÉNIÈRE'S DISEASE

SIR,—In connection with your leading article last week I would like to emphasise the enormous help that has been derived as to the nature and causes of attacks of Meniere's vertigo by the careful post-mortem study of the findings in fatal cases of acute apoplectiform vertigo in patients with myelocytic leukæmia This was obvious from my article with Mr Rickard Lake entitled Acute Ménière's Symptoms in Splenomedullary Leucocythæmia in *Medico Chirurgical Transactions* (1900, 83, 185) In this we were greatly helped by Dr Louis Waldstein, then resident in London though not practising The most striking cases from the literature of the subject were referred to, and our communication was followed on the same evening by one on an analogous case by F W Mott (later Sir Frederick Mott)

London N W 1   F PARKES WEBER

SHORTAGE OF RADIOGRAPHERS

SIR,—Dr Illingworth (Jan 5) has given his views on the causes of the shortage of radiographers As some of his statements are inaccurate and misleading,-I should like to reply

Firstly, the dissatisfaction felt by radiographers towards their "inadequate remuneration" is by no means confined to "a few male radiographers" There is overwhelming evidence at the society's headquarters that this dissatisfaction is universal throughout the profession At a meeting held recently in London to discuss the disastrous salary award made in November, the number of women attending greatly outnumbered the men and they were by no means silent observers but showed a keen interest by their questions and suggestions

Secondly, the Society of Radiographers has no regulations governing the age at which a student radiographer may commence training although no student may qualify before reaching the age of 20—a reasonable age, bearing in mind the responsibility of the radiographer when dealing with sick and injured patients, more especially now that the danger of excessive radiation is so much to the fore

Thirdly, the Society of Radiographers, along with other professional societies, has been required to submit to the Minister of Health its syllabus of training, educational standard details of examinations, and the composition of its board of examiners These have been approved by the Minister More recently the educational requirements were broadened in order to assist recruitment, and this step was also approved by the Minister

The Society's board of examiners is composed of radiologists, radiotherapists, physicists, and X-ray technologists, many of whom are not members of the society, together with radiographers This board is virtually an autonomous body, and it is ludicrous to suggest that the society, makes its examinations too difficult, thus limiting entry into the profession Dr Illingworth himself has for some time been one of the society's examiners

It is universally accepted that those who understand the principles underlying the construction of apparatus use it to the best advantage, and the syllabus in physics and apparatus was drawn up with this in mind It is the duty of this society to see that radiographers have this basic knowledge, especially when they have to handle complicated and very costly apparatus which is capable of doing irreparable harm to both the patients and themselves

It is to the advantage of the radiologist and the medical profession generally to have a fully staffed department of highly qualified, competent radiographers able to carry out their duties efficiently, and to pay proper attention to the care and comfort of the patient and thus enable diagnosis to be confirmed or to record progress with the minimum radiation exposure to the patient

Finally, the post of superintendent radiographer is essential as on this radiographer falls the responsibility of the day to day administration of the department Even in departments where a full-time consultant radiologist is appointed, a great deal of responsibility falls on the superintendent radiographer, and in the majority of hospitals where the consultant is only part-time the superintendent radiographer often has to accept the responsibility of running the department and for the care and welfare of the patients as well as maintaining a high standard of radiography

The standards of training required by the Society of Radiographers are reputed to be the best in the world and in no small way contribute to the high standard of the radiological services of this country Nothing should be done to lower this standard or the service to the patients

Society of Radiographers,
32 Welbeck Street London, W 1   MARY VAUGHAN
President

SIR,—I can but suppose that Dr Illingworth wrote with his tongue in his cheek Should this not be so, it must be inferred that he would favour the complete disbandment, not only of the Society of Radiographers, but of all auxiliary medical examining bodies If physics is superfluous to radiography, is it any more necessary for training for the radiological diploma ?

A superintendent's duties are varied, and the smooth running of the department and the contentedness of the staff depend possibly more on his handling than on any other factor He provides the liaison between the radiologist and the remainder of the staff If Dr Illingworth feels himself capable of taking over the technical and administrative duties of the superintendent radiographer in addition to those of radiology in a reasonably large department, then I must take off my hat to him

Almost all superintendent radiographers must, of necessity, be capable of carrying out "running repairs" As a correspondent has already said, we are not all within easy reach of the servicing engineer, nor can we afford to let a major piece of apparatus lie idle Incidentally, these "running repairs" save managements some hundreds of pounds annually—a fact which most managements are totally unaware of

General Infirmary,
Salisbury   K CRUICKSHANK

RETURN TO PLANNING

SIR,—Arising out of your leading article and correspondence to date on this matter, two big points appear to have arisen, firstly, the plight of the young married registrars or senior hospital medical officers, often with children, whose remuneration is so inadequate, secondly, the whole question of merit awards

Surely if there is to be a return to planning, there should be an abolition of all merit awards, which must inevitably encumber the supertax paying consultant Let these vast sums of money handed over as merit awards (the large portion of which is handed back in tax to the Government) be spread amongst the well-deserving registrars and senior medical officers

Windsor   D MAXWELL

PROLONGED PYREXIA IN CHILDREN

SIR,—In reply to Dr Wallis, who wrote last week, my reasons for not considering brucellosis as a diagnosis were not the upper respiratory symptoms or the one negative agglutination test, but the occurrence of these cases of pyrexia starting at a time when an epidemic of influenza was present in the town and surrounding countryside Moreover none of the patients had a rash, palpable spleen, or neutropenia, and the temperature chart did not show an undulant type of fever The milk is pasteurised non-tuberculin tested

In the absence of serological proof, it is possible to suggest that the epidemic in the children's home, although following an identical clinical pattern, was different from that in the surrounding area If this is so, it is a most remarkable coincidence

Chipping Norton
Oxon   F E JAMES

RAISED C S F -SUGAR LEVELS

SIR,—I wonder if any of your correspondents can give me some information about raised levels of sugar in the cerebrospinal fluid (C S F)

We deal with a large number of C S F s, as this is a fever hospital and a poliomyelitis unit Off and on over the past few years we have come across the odd C S F sugar above the normal limits—usually about *120–140* mg per *100* ml— and, as the C S F pressure was raised, it was assumed that this merely *reflected the blood sugar level at the time* Unfortunately no blood sugar estimations were performed In every case a repeat C S F after clinical recovery gave a result within normal limits Recently, however, we had a very high result—180 mg per 100 ml —and a blood sugar taken simultaneously was only 88 mg per 100 ml The patient, a case of bulbar poliomyelitis, has not yet sufficiently recovered to make a repeat lumbar puncture worth while

I know of no reference to such unusual results

Rush Green Hospital,
Romford, Essex

F BRAFIELD

CARDIAC ARREST

SIR,—*Some recent papers on cardiac arrest on the* operating-table,[1-3] and the letter from Professor Stammers last week setting the modern treatment in its historical perspective, have focused attention on this dire calamity May I plead for four practical measures which would lessen the mortality of the condition

1 The surgeons and anæsthetists in each hospital should draft a short plan for action to be taken in case of sudden cardiac arrest, and this should be displayed in the operating-suite and be familiar to all who work there, especially the junior surgeons and anæsthetists

2 All surgeons, no matter what their specialty, should, together with their junior colleagues, go to the post mortem room, say, once a year to familiarise themselves with the technique of transthoracic cardiac massage on the cadaver

3 Each operating theatre should be equipped with a drum containing the sterile instruments, retractors, syringes, and ampoules needed in the emergency

4 Each theatre suite should be provided with an electrical defibrillator

To be fully prepared to meet the emergency is to be more than half-way towards its successful management

Southend on Sea

J ALFRED LEE

A NEWSPAPER FOR THE PARTLY SIGHTED ?

SIR,—In everyday work in a general practice one is struck by the number of patients who have become "partly sighted" in their late sixties and early seventies Sudden and permanent deterioration in vision may follow a stroke of one type or another, or slow deterioration may be due to cardiovascular degeneration embracing conditions responsible for retinal failure

Often the patient is intelligent and mentally active but forced into early retirement by the physical infirmities consequent upon cerebrovascular degeneration At one moment the patient may be at the head of a large business or in control of a school, and the next he is bedridden, eclipsed and useless The plight of these people is the worse because their one link with the rest *of the world has been severed They can no longer read*

I have several such patients who struggle with the daily nationals and their favourite journals but can read only the headlines How many are heard to say "I can read the headlines, but I cannot make anything of the rest ?"

The purpose of my letter is to ask if it is possible to print a weekly newspaper all in headline type for these patients There are, I calculate, at least 100,000 people in Great Britain whose sight is sufficient to read large headline type but not sufficient to read ordinary letter press What a boon it would be to these people to be able to read all the news themselves and feel that once again they are in touch with the outside world

A large magnifying glass is not the solution to this problem The field of vision is reduced too greatly and there is too much peripheral distortion to make reading anything but a labour

Is there a newspaper printed all in headline type ? If not, could any institution be persuaded to try the experiment ? What an opportunity for a repressed journalist to publish ten thousand words in headlines and to feel he is doing good at the same time

Sheffield

E C ATKINSON

A "POST-ACUTE" HOSPITAL

SIR,—According to a newspaper report cited in your news columns last week, Mundesley Sanatorium is to be taken over by the East Anglian Regional Hospital Board as a "post acute" hospital

"Acute" means "coming sharply to a crisis, not chronic" *(O E D)* We already have "sub acute" and "hyper-acute" (or, for the purist, "super acute"), but "post acute" seems to be new I take it that post subacute and post chronic patients will not qualify for admission, so let us hope that early ambulation on the Norfolk beaches will meet with good patient acceptance from the post-acutes

Institute of Diseases
of the Chest

J R BIGNALL

YOGURT IN GASTRO-ENTERITIS OF INFANCY

SIR,—We have read Dr Raffle's letter[1] with interest as we have used yogurt for the treatment of gastro enteritis in a number of patients We have found *that* commercial yogurt preparations differ in their efficacy, and possibly this is due to variation in the microflora between the different yogurt preparations

The normal yogurt today consists of a roughly equal mixture of *Lactobacillus bulgaricus* and *Streptococcus thermophilus L bulgaricus* is the organism originally publicised by Metchnikoff, but it has been shown by numerous investigators[2-4] that *L bulgaricus* not only cannot proliferate in the gut but rapidly dies out For lactobacillus therapy, therefore (as distinct from yogurt as a food), *L acidophilus*, which can be regarded as a normal inhabitant of the intestine, should be used Either a pure culture of *L acidophilus* (acidophilus milk) or a yogurt containing an appreciable proportion (e g , 10%) of *L acidophilus* should be used for the treatment of gastro enteritis and similar complaints

Although the attitude of practitioners generally towards cultured milks is very mixed, there is considerable experimental evidence that for some complaints (e g , gastro enteritis, colitis, constipation, biliary disorders, flatulence, malaise, migraine, nervous fatigue) cultured milks, and especially acidophilus milk, can be extremely valuable[4-6] Yogurt and acidophilus milk can often be taken by those who cannot take ordinary milk It thus has value as a food for those unable to digest milk The curd formed in the stomach by cultured milks is much finer than that formed by milk[6,7]

Many examples of the value of cultured milks supported by sound experimental evidence are given in the literature We may quote in this connection the observations of Comly[8] and Mayon White[9] on deaths of infants from methæmoglobinæmia as the result of bacterial reduction of nitrate in water, and the use of yogurt as a

London W 1

SOCIAL STRESSES SEEN IN GENERAL PRACTICE

SIR,—The family doctor sees certain symptoms and complaints recurring under similar conditions He can, if he looks for them, recognise particular social conditions which favour particular kinds of illness The following are three examples, all of them (as it happens) chiefly affecting men 40 to 60 years of age

Football Matches

People of all social classes have become weekly devotees of the local football game and, fit or not, will attend a match in any weather

Some patients, though suffering from a feverish cold or acute bronchitis, thus expose themselves against their better knowledge to damp cold weather They may even be compelled to be absent from work for this reason, or, by following their urge, turn trivial illnesses into more serious ones

More important are those with coronary disease The football-grounds are often further from the car-park or bus-stop than they usually have to walk, they hurry and become members of the herd, rushing to their stands, and often have to climb many steep steps, enduring a physical effort they would do their utmost to avoid at any other time In addition, their emotional excitement leads to further strain I find that patients who usually need perhaps 2–3 glyceryl trinitrate tablets a day may have to take 8 during each match I have records of several patients in whom a first or a fatal attack of coronary thrombosis can be directly attributed to attendance at a match

Lodge Meetings

Looking at the history of middle-aged patients with nervous breakdown, hypertension, or coronary disease, it is surprising how many regularly attend Masonic meetings and break down in preparing themselves for high office in their lodge At an age when they are out of mental training for such work, they have to learn by heart long passages of ceremonial formulæ and speeches Sometimes for a year or more, their free time, and often long night hours, are devoted to memorising long passages, and this can lead to continuous anxiety Ambition, pride, and fear of failure usually keep them going until their object is achieved, and then they break down in utter exhaustion, often with an anxiety state or coronary thrombosis The ceremony itself, with perhaps two hours in a locked or closed room, causes acute anxiety symptoms

These lodge activities are rarely disclosed spontaneously by the patient themselves, but once attention has been drawn to them (usually by their wives) the strain is admitted Such a strain is undoubtedly more significant in breakdowns than has been realised The family doctor can often prevent these men, when they are seen in time, from doing something which will be detrimental to their health Perhaps some lodges would allow their members to read their ceremonial addresses and not insist that everything must be spoken from memory

Income-tax Difficulties

In my third group are those who fear, or are actually in trouble with, the income-tax authorities Their symptoms of sleeplessness, nervousness, lack of concentration, and feeling run down, are so characteristic that one can almost ask them outright whether they have any income-tax troubles An interesting point is that these people do not start worrying until they are in fear of being found out or are already in difficulties The severity of symptoms is not always in proportion to the gravity of the offence It seems particularly to depend on the length of time taken to settle the problem with the authorities and even if the material effect of the settlement is less ruinous than had been feared, the effect on physical and mental health is often devastating No treatment is likely to do much good until the authorities have reached their decision, and the only help a family doctor can give is friendly advice to disclose everything in order to save the patient's best asset, his health

I offer these as illustrations of social strains which are obvious when once observed and which perhaps need more attention than they generally receive

Manchester   R FRIEDLAENDER

VAGITUS UTERINUS

SIR,—Mr Russell's article (Jan 19) reminded me that I encountered this phenomenon about 1926 During a forceps delivery, before the head was visible, the baby "squawked" The midwife, never an encouraging type, muttered in my ear "you've done it all right, this time, doctor!" However, all ended well

Middlesbrough   JOHN CAHILL

THE FUTURE OF NURSING

SIR,—I was relieved to see the letter from Miss M M Edwards last week and the views she has expressed on the right relationship between doctor and nurse

As district nurses we willingly work under the direction of a doctor in carrying out the treatments he orders and reporting to him on his patients We would not have it otherwise, recognising that the doctor has medical knowledge, skill, and responsibilities far beyond those of a nurse, and that he is her respected colleague

General practitioners, from whom 90% of the district nurse's patients are referred, have, since the Queen's Institute was first organised nationally 70 years ago, worked in harmonious partnership with district nurses These nurses feel no need, even when they are district nurse midwives and health visitors, to proclaim that "they are practitioners in their own right"

When their relationship is unquestioned, from long experience it is found that the doctor readily leaves to the nurse, with or without consultation, full responsibility for the nursing comfort, morale, hygiene, and health teaching of his patients, and for obtaining social help He knows that the nurse will keep him informed of the patient's progress, and of when his medical help is needed urgently Both work with one objective, but it is the doctor who shoulders the ultimate and greater responsibility

The training of a doctor is extensive and requires to be of a high university level for the knowledge and skill he must attain It is wasteful if he undertakes work, except in expediency, which a nurse could do The training of a State-registered nurse is less extensive, and it is in my opinion doubtful if it requires to be of a university level even for the few leaders of the nursing profession It seems that the motives suggesting that there should be more nurses with university degrees are mainly "to keep up with the Joneses" in other countries, many of which have universities of very different standards from those in this country It seems wasteful that the precious places in the few universities of Great Britain should be taken up by potential nurses

The well trained mind, capable of critical analysis, is of undoubted value to any nurse whose work requires her to administer or to teach If, as is the case with a few district nurses, she happens to have a degree before becoming a nurse, she yet may have no desire to administer or to teach Even if she does desire it, a specially designed advanced nursing course after registration seems likely to be more helpful than her previous university degree

It is wasteful also, if State registered nurses whose basic education requires to be good and whose training is long and comprehensive, are used for work, except when unavoidable, which a State enrolled assistant nurse could undertake A considerable increase in the employ-

RAISED C S F -SUGAR LEVELS

SIR,—I wonder if any of your correspondents can give me some information about raised levels of sugar in the cerebrospinal fluid (C S F)

We deal with a large number of C S F s, as this is a fever hospital and a poliomyelitis unit Off and on over the past few years we have come across the odd C S F sugar above the normal limits—usually about 120–140 mg per 100 ml —and, as the C S F pressure was raised, it was assumed that this merely reflected the blood sugar level at the time Unfortunately no blood sugar estimations were performed In every case a repeat C S F after clinical recovery gave a result within normal limits Recently, however, we had a very high result—180 mg per 100 ml —and a blood sugar taken simultaneously was only 88 mg per 100 ml The patient, a case of bulbar poliomyelitis, has not yet sufficiently recovered to make a repeat lumbar puncture worth while

I know of no reference to such unusual results

CARDIAC ARREST

SIR,—Some recent papers on cardiac arrest on the operating-table,[1-3] and the letter from Professor Stammers last week setting the modern treatment in its historical perspective, have focused attention on this dire calamity May I plead for four practical measures which would lessen the mortality of the condition

1 The surgeons and anæsthetists in each hospital should draft a short plan for action to be taken in case of sudden cardiac arrest, and this should be displayed in the operating-suite and be familiar to all who work there, especially the junior surgeons and anæsthetists

2 All surgeons, no matter what their specialty, should, together with their junior colleagues, go to the post mortem room, say, once a year to familiarise themselves with the technique of transthoracic cardiac massage on the cadaver

3 Each operating theatre should be equipped with a drum containing the sterile instruments, retractors, syringes, and ampoules needed in the emergency

4 Each theatre suite should be provided with an electrical defibrillator

To be fully prepared to meet the emergency is to be more than half way towards its successful management

J ALFRED LEE

A NEWSPAPER FOR THE PARTLY SIGHTED ?

SIR,—In everyday work in a general practice one is struck by the number of patients who have become "partly sighted" in their late sixties and early seventies Sudden and permanent deterioration in vision may follow a stroke of one type or another, or slow deterioration may be due to cardiovascular degeneration embracing conditions responsible for retinal failure

Often the patient is intelligent and mentally active but forced into early retirement by the physical infirmities consequent upon cerebrovascular degeneration At one moment the patient may be at the head of a large business or in control of a school, and the next he is bedridden, eclipsed and useless The plight of these people is the worse because their one link with the rest of the world has been severed They can no longer read

I have several such patients who struggle with the daily nationals and their favourite journals but can read only the headlines How many are heard to say "I can read the headlines, but I cannot make anything of the rest ?"

The purpose of my letter is to ask if it is possible to print a weekly newspaper all in headline type for these patients There are, I calculate, at least 100,000 people in Great Britain whose sight is sufficient to read large headline type but not sufficient to read ordinary letter press What a boon it would be to these people to be able to read all the news themselves and feel that once again they are in touch with the outside world

A large magnifying glass is not the solution to the problem The field of vision is reduced too greatly and there is too much peripheral distortion to make reading anything but a labour

Is there a newspaper printed all in headline type ? If not, could any institution be persuaded to try the experiment ? What an opportunity for a repressed journalist to publish ten thousand words in headlines and to feel he is doing good at the same time

J R BIGNALL

YOGURT IN GASTRO-ENTERITIS OF INFANCY

SIR,—We have read Dr Raffle's letter[1] with interest as we have used yogurt for the treatment of gastro enteritis in a number of patients We have found that commercial yogurt preparations differ in their efficacy, and possibly this is due to variation in the microflora between the different yogurt preparations

The normal yogurt today consists of a roughly equal mixture of *Lactobacillus bulgaricus* and *Streptococcus thermophilus* *L bulgaricus* is the organism originally publicised by Metchnikoff, but it has been shown by numerous investigators[2-4] that *L bulgaricus* not only cannot proliferate in the gut but rapidly dies out For lactobacillus therapy, therefore (as distinct from yogurt as a food), *L acidophilus*, which can be regarded as a normal inhabitant of the intestine, should be used Either a pure culture of *L acidophilus* (acidophilus milk) or a yogurt containing an appreciable proportion (e g , 10%) of *L acidophilus* should be used for the treatment of gastro enteritis and similar complaints

Although the attitude of practitioners generally towards cultured milks is very mixed, there is considerable experimental evidence that for some complaints (e g , gastro enteritis, colitis, constipation, biliary disorders, flatulence, malaise, migraine, nervous fatigue) cultured milks, and especially acidophilus milk, can be extremely valuable[4-6] Yogurt and acidophilus milk can often be taken by those who cannot take ordinary milk It thus has value as a food for those unable to digest milk The curd formed in the stomach by cultured milks is much finer than that formed by milk[5,7]

Many examples of the value of cultured milks supported by sound experimental evidence are given in the literature We may quote in this connection the observations of Comly[8] and Mayon-White[9] on deaths of infants from methæmoglobinæmia as the result of bacterial reduction of nitrate in water, and the use of yogurt as a

SOCIAL STRESSES SEEN IN GENERAL PRACTICE

SIR,—The family doctor sees certain symptoms and complaints recurring under similar conditions He can, if he looks for them, recognise particular social conditions which favour particular kinds of illness The following are three examples, all of them (as it happens) chiefly affecting men 40 to 60 years of age

Football Matches

People of all social classes have become weekly devotees of the local football game and, fit or not, will attend a match in any weather

Some patients, though suffering from a feverish cold or acute bronchitis, thus expose themselves against their better knowledge to damp cold weather They may even be compelled to be absent from work for this reason, or, by following their urge, turn trivial illnesses into more serious ones

More important are those with coronary disease The football-grounds are often further from the car-park or bus-stop than they usually have to walk; they hurry and become members of the herd, rushing to their stands, and often have to climb many steep steps, enduring a physical effort they would do their utmost to avoid at any other time In addition, their emotional excitement leads to further strain I find that patients who usually need perhaps 2-3 glyceryl trinitrate tablets a day may have to take 8 during each match I have records of several patients in whom a first or a fatal attack of coronary thrombosis can be directly attributed to attendance at a match

Lodge Meetings

Looking at the history of middle-aged patients with nervous breakdown, hypertension, or coronary disease, it is surprising how many regularly attend Masonic meetings and break down in preparing themselves for high office in their lodge At an age when they are out of mental training for such work, they have to learn by heart long passages of ceremonial formulæ and speeches Sometimes for a year or more, their free time, and often long night hours, are devoted to memorising long passages, and this can lead to continuous anxiety Ambition, pride, and fear of failure usually keep them going until their object is achieved, and then they break down in utter exhaustion, often with an anxiety state or coronary thrombosis The ceremony itself, with perhaps two hours in a locked or closed room, causes acute anxiety symptoms

These lodge activities are rarely disclosed spontaneously by the patient themselves, but once attention has been drawn to them (usually by their wives) the strain is admitted Such a strain is undoubtedly more significant in breakdowns than has been realised The family doctor can often prevent these men, when they are seen in time, from doing something which will be detrimental to their health Perhaps some lodges would allow their members to read their ceremonial addresses and not insist that everything must be spoken from memory

Income-tax Difficulties

In my third group are those who fear, or are actually in trouble with the income-tax authorities Their symptoms of sleeplessness nervousness, lack of concentration, and feeling run down, are so characteristic that one can almost ask them outright whether they have any income tax troubles An interesting point is that these people do not start worrying until they are in fear of being found out or are already in difficulties The severity of symptoms is not always in proportion to the gravity of the offence It seems particularly to depend on the length of time taken to settle the problem with the authorities and even if the material effect of the settlement is less ruinous than had been feared, the effect on physical and mental health is often devastating No treatment is likely to do much good until the authorities have reached their decision, and the only help a family doctor can give is friendly advice to disclose everything in order to save the patient's best asset, his health

I offer these as illustrations of social strains which are obvious when once observed and which perhaps need more attention than they generally receive

THE FUTURE OF NURSING

SIR,—I was relieved to see the letter from Miss M M Edwards last week and the views she has expressed on the right relationship between doctor and nurse

As district nurses we willingly work under the direction of a doctor in carrying out the treatments he orders and reporting to him on his patients We would not have it otherwise, recognising that the doctor has medical knowledge, skill, and responsibilities far beyond those of a nurse, and that he is her respected colleague

General practitioners, from whom 90% of the district nurse's patients are referred, have, since the Queen's Institute was first organised nationally 70 years ago, worked in harmonious partnership with district nurses These nurses feel no need, even when they are district nurse midwives and health visitors, to proclaim that "they are practitioners in their own right"

When their relationship is unquestioned, from long experience it is found that the doctor readily leaves to the nurse, with or without consultation, full responsibility for the nursing comfort, morale, hygiene, and health teaching of his patients, and for obtaining social help He knows that the nurse will keep him informed of the patient's progress, and of when his medical help is needed urgently Both work with one objective, but it is the doctor who shoulders the ultimate and greater responsibility

The training of a doctor is extensive and requires to be of a high university level for the knowledge and skill he must attain It is wasteful if he undertakes work, except in expediency, which a nurse could do The training of a State registered nurse is less extensive, and it is in my opinion doubtful if it requires to be of a university level even for the few leaders of the nursing profession It seems that the motives suggesting that there should be more nurses with university degrees are mainly "to keep up with the Joneses" in other countries, many of which have universities of very different standards from those in this country It seems wasteful that the precious places in the few universities of Great Britain should be taken up by potential nurses

The well trained mind, capable of critical analysis, is of undoubted value to any nurse whose work requires her to administer or to teach If, as is the case with a few district nurses, she happens to have a degree before becoming a nurse, she yet may have no desire to administer or to teach Even if she does desire it, a specially designed advanced nursing course after registration seems likely to be more helpful than her previous university degree

It is wasteful also, if State registered nurses, whose basic education requires to be good and whose training is long and comprehensive are used for work, except when unavoidable, which a State enrolled assistant nurse could undertake A considerable increase in the employment of assistant nurses working in partnership and with the guidance of State-registered nurses seems to be essential

---

[10] Orla Jensen S, et al *J Danish Acad Sci Lit* 1945 111 4

The future of the nursing service will be strengthened if the concern of doctors in the training of the State-registered nurse is welcomed and encouraged, and if the latter concern themselves more than at present with the wider training of the assistant nurse

Let each one choose the career within his or her ability or in which can be found satisfaction, recognising the other's greater knowledge rather than considering lowering the standards of each

SUCCESSFUL ABSENTEES

SIR,—Your readers have noted with interest the innovation at St Andrews University (reported in your columns last week) whereby the final examinations may be passed in the absence of the candidate This innovation has no doubt been designed to benefit those who have also taken their medical course in absentia

Westminster Medical School,
London, S W 1
ANDREW SHERRINGTON

SYRINGE CARRIER

SIR,—Most people with experience of syringe carriers for dry sterilisation will agree with Dr McDonald and Mr Pirnie (Jan 26) that the syringe carrier suggested by Dr Lerman (Jan 12) is unlikely to solve the problems of the *anæsthetist But one cannot allow their dogmatic* attack upon multiple syringe carriers to go unchallenged

In our experience a properly designed multiple syringe container is the only answer to the many problems, organisational, technical and financial, involved in running a syringe service which will cover all hospital departments, small outlying hospitals, the general practitioners, and the laboratory itself After some years of using the Kingston type of multiple syringe carrier,[1] and issuing it to some hundreds of users, we find it has none of the disadvantages alleged by Dr McDonald and Mr Pirnie

Firstly, it need not " contain a fixed set of syringes which may or may not accord with the demands of varying circumstances " Just because our normal pack contains a variety of syringes—2, 5, 10, and 20 ml —it answers most demands But the normal pack can easily be changed to meet special needs As our anæsthetists do not all have the same views as to what is best we have now had a certain number of boxes made with sides in distinctive colours (red, blue, and green) and by altering the clips can issue packs with all one size—and the theatre carries a stock of each Other users have other needs and can have a box specially packed to meet them

Secondly, in our experience with this type of box, which was designed with these points in view, the contents are *not* "rendered potentially non sterile on first opening" Nor can the needles or syringes be contaminated by " air, droplets, or hands " As for the " life " of one boxful our turnover of *3500* syringes a week *ensures that* this is not prolonged, but we do not in any case require all the syringes to be used before a box is returned It is a very simple operation to replace a *few* used *syringes* and sterilise the lot

Thirdly, in the Kingston box the sign of sterility is the continued presence of the cotton wool plug round the needle To use the syringe this seal must be removed, and once removed it is quite clear that the syringe has been used (or at any rate taken out and exposed to air even if, for any reason, not used) In practice, after turning these boxes over hundreds of times, after their use by all grades of medical and nursing staff, after use for all hospital purposes, we are quite certain of their sterility and continuing sterility

The problems of a syringe service which neither multiple nor single pack will absolutely abolish—the needle that looks sharp but is not, the plunger that has stuck, the imperfect fitting of needle to syringes—all remain unless one uses an extravagant number of people on the job Our multiple pack has reduced these to a minimum because it saves time, and it has reduced costs because breakages are only about one per cent of all the syringes issued

Parliament

The Right Kind of Bed

MOST old people lead contented lives with their families or friends but, as Lord AMULREE pointed out in the House of Lords on Jan 22, many of the small group of old people who live alone fall into the unfortunate administrative gap between the National Health Service Act and the National Assistance Act 40% of the old people who applied for admission to hospital, he said, belonged to this group, and after their hospital treatment it was difficult to find anywhere for them to go They were not sick, they were suffering from profound disability, and though local authorities were providing more accommodation for people who were on the borderline between being really fit and in need of hospital accommodation, there was still not enough As a result, many people were forced to remain in hospital, occupying beds which were urgently needed for the care of the sick, and which cost £12–15 a week each

Lord Amulree did not for a moment advocate a return to the old poor law, but one principle in it which he thought was valuable was that people in need of care and attention, whether sick or well, were under the same authority One of the disadvantages of the present division was that old people were often reluctant to go into a welfare home because for them it still had, however mistakenly, a flavour of the workhouse Another was that the welfare authorities would not accept people who were not fit In his view, while *accommoda*tion was so straitened, it should be used for the people who really needed it In 1954, 65,000 old people were living in these *homes* compared with 47,000 in 1945 Were there some people living in these homes unnecessarily? Could some of them, with the help of better domiciliary services, *not live on their own, and free the homes* for the less fit? Indeed, if the right people were kept in the beds we had, he doubted if any big increase was needed

We should get away from the terms " acute sick " and " chronic sick " A more useful division, he suggested, was people who were sick and needed medical care and treatment, and people who were disabled and needed different care and attention He also thought it would help if regional boards and local authorities made joint appointments so that the same doctors looked after old people in hospitals and the local-authority homes, and if the welfare services could be transferred to the health committee of the local authority

Lord COTTESLOE, in his work as chairman of the North West Metropolitan Regional Hospital Board, had seen something of the difficulties which arose from shortage of accommodation He agreed that the wrong people were often in what beds there were To his mind the greatest cause for concern was the substantial number of mental-hospital patients who should never have gone into a mental hospital at all but should have found a place in a welfare home Once these people had been sent to a mental hospital it was difficult to transplant them to a home He was anxious that we should be careful that for the future no old people who were merely a little confused should find their way into the mental hospitals

The EARL OF HOME, the secretary of State for Commonwealth Relations, replying for the Government, offered some support for Lord Amulree's view In 1955 some 4500 elderly people who no longer needed full hospital treatment occupied hospital beds On the other hand, there were 2000 old people who would be *better* in hospital than in the premises in which they were housed So by transfers, and if additional premises and home helps were available, some 2500 beds could be used to better purpose for others in more urgent need

Reviewing what had been done for old people he said that in the past nine years 70 geriatric units had been started, while the number of elderly outpatients had risen from 7000 in 1950 to 27,000 in 1955 Local authorities had opened 900 small residential homes The home-nursing service made 12$^1/_2$ million visits a year to old people We could thus, he thought, conscientiously say that we were not neglecting the old But it would be unrealistic against the background of the national income to expect that there should be a great increase in capital investment Further help for the elderly must rest on greater efficiency in organisation, greater coördination of the efforts of hospitals, doctors, and welfare authorities, and greater appreciation by the local authorities of the needs of the old In 1954–56 the Ministry of Health's officers made a survey of the services for the elderly sick throughout England and Wales The results had been assessed on a national basis and the Minister proposed to issue memoranda with suggestions arising from the survey and to send them to all hospitals and local authorities

QUESTION TIME

Doctors' Remuneration

Mr **Marcus Lipton** asked the Minister of Health what negotiations were pending to increase the salaries of doctors —Mr **Dennis Vosper** replied The Secretary of State for Scotland and I have agreed to meet representatives of the profession towards the middle of February For the present, I have no statement to make

Mr **John Rankin** asked the Minister if he was now prepared to accept the contractual obligation implied in the Spens report as the basis of all future salary negotiations with the medical profession? Mr **Vosper** I am advised that no legal contractual obligation exists Mr **Rankin** Does the Minister not realise that now he has properly decided to meet the doctors in negotiations over their claim for higher remuneration, it will be necessary for him to face up to what are called the implications, alleged or otherwise, of the Spens reports? Would it not be wise of him to take this matter into consideration in the negotiations? Mr **Vosper** I have just said in my original reply that no legal contractual obligation exists That opinion was conveyed to the doctors at an earlier meeting, and when they meet in February they will be well aware of the position Mr **Rankin** Is the Minister not aware that this is one of the points which has caused every scalpel in Scotland at least to be drawn during the week end and that there will be no satisfactory issue unless the matter is dealt with? The doctors do not accept the explanation he has given Mr **Vosper** I have already said that I will meet the doctors, and I shall look forward to that meeting, but I shall not be meeting them on the basis that a legal contractual obligation exists

Cigarette-smoking

Mr **Lipton** asked the Minister whether he would appoint a select committee to consider what immediate and practical steps can be taken to reduce cigarette smoking —Mr **Vosper** replied I do not consider that a select committee would be an appropriate body for this purpose

Mr **Somerville Hastings** Short of appointing a Royal Commission, does not the Minister feel that the evidence is sufficiently strong for something definite to be done by his department? Ought not young people and children in the schools at any rate to be warned of the dangers of cigarette smoking? Mr **Vosper** I do intend to look further into this matter and to take the advice of those concerned I do not believe at the moment that a select committee would be the right vehicle The Minister of Education has of course, recently issued further advice to the schools

Prices of Pharmaceutical Products

Replying to a question Mr **Vosper** said that the current negotiations with the pharmaceutical industry concerned the prices of proprietary preparations Discussions had recently been concluded and in the light of these the industry had revised their proposals, which he was now considering

Prescription Charges

Mr **S S Awbery** asked the Minister if he was aware that many chronic sick cancer patients diabetics those suffering from ulcers and others with long standing complaints are not receiving the treatment they need and which was intended by the National Health Act, 1948, that chemists are reporting a reduction of 50% in the prescriptions since the new charges were made on Dec 1 Mr **Vosper** I have no evidence from professional organisations or elsewhere that patients are not receiving the treatment they need, or that there has been such a reduction in prescriptions dispensed

Number of Patients and Hospital Salaries

Mr **C J A Doughty** asked the Minister which officials of mental hospitals were responsible for the discharge of patients, on what basis they were remunerated, and whether their remuneration was related in any way to the number of patients in the hospital —Mr **Vosper** replied No official is authorised to discharge a patient in a mental hospital, but any two members of the hospital management committee when ordering the discharge of a temporary or certified patient must do so with the advice in writing of the medical superintendent The salary of medical superintendents is generally based on length of service in their clinical grade and not on the number of patients Mr **Doughty** It therefore follows does it not, that if beds in a mental hospital are empty, the officials responsible for the discharge of patients suffer no financial loss? Mr **Vosper** Yes, that is true

Mr **N N Dodds** asked the Minister on what basis the salaries of senior nursing officers in mental institutions were fixed —Mr **Vosper** replied The salaries of both matrons and chief male nurses in mental and mental deficiency hospitals are determined by the status of the hospital and the number of staffed beds for which the officer is responsible The classification of deputy matrons and deputy chief male nurses for salary purposes is governed by that of their chiefs

Health of Immigrants

Captain **H B Kerby** asked the Minister of Health if he was aware that Great Britain was the only Commonwealth country that any immigrant could enter without producing a certificate of good health, and what steps he proposed taking to safeguard Great Britain from imported communicable diseases Mr **Vosper** replied The existing Public Health (Ships) and (Aircraft) Regulations, 1952, give wide powers to port medical officers to deal with any case or suspected case of communicable disease arriving in this country In addition, alien immigrants may be medically examined under the Aliens Order, 1953

Obituary

JOHN McGRATH

M Sc, M D N U I

The death, on Jan 11, of John McGrath, professor of pathology and bacteriology and dean of the faculty of medicine in University College, Dublin, leaves a gap in Irish medical life

Born in co Waterford in 1901 he was educated at Clongowes Wood College, graduating B SC at University College, Dublin, in 1921 The following year he proceeded M SC and he graduated in medicine in 1925 He spent some years abroad in postgraduate study in Vienna Heidelberg, and Mannheim before returning to Dublin where he was appointed assistant pathologist and biochemist at St Vincent's Hospital with which he was to be associated for the next quarter of a century

In 1929 he was appointed lecturer in medical jurisprudence in University College and also State pathologist and in 1933 he was called to the Irish Bar It was in forensic medicine that he became, perhaps, most widely known, and there can have been few courthouses in the country in which he had not given evidence He studied every case with scrupulous attention to detail, and the Irish courts were fortunate in having at their disposal a man of such vast experience whose evidence was always so clearly expressed

He was an exceptionally good lecturer, and for many years he was external examiner to Dublin University and to the Queen's University of Belfast In 1952 he was appointed to the chair of pathology and bacteriology at University College, Dublin and last year he was elected dean of the faculty of medicine Unfortunately, almost immediately afterwards he became seriously ill

He was a member of the Royal Irish Academy, of the senate of the National University of Ireland and of the

Medical Registration Council, and he had been president of the section of pathology of the Royal Academy of Medicine in Ireland During the early thirties he was one of those responsible for the foundation of the Medical Research Council of Ireland, of which he remained treasurer until his death He was the first chairman of the National Blood Transfusion Association and was for many years pathologist to the National Maternity Hospital He was a former assistant editor of the *Irish Journal of Medical Science*

Such a busy professional life might well have left little scope for other activities, but his term as president of the Royal Zoological Society of Ireland—which controls the Dublin Zoo—was outstandingly successful He was a keen fisherman and an enthusiastic photographer, and until lately one of his greatest pleasures was winter sports He could speak with authority of most parts of Europe, for his holidays were almost always spent in travel, yet few can have known their own countryside so well

CHARLES NOON

O B E , F R C S

Mr Noon, senior consulting surgeon to the Norfolk and Norwich Hospital, died on Jan 19 at the age of 71

He was born in Leicester, where his father, the late Samuel Bilson Noon, practised as a solicitor He was educated at Blairlodge, Stirlingshire, and studied medicine at St Bartholomew's Hospital After qualifying in 1910 he spent the next three years in house-posts at Barts, and his chiefs included Holburt Waring, Horder, Charles Gordon-Watson, and Francis Champneys In 1914 he took the F R C S and the following year he was appointed chief assistant to the gynæcological department at Barts

Noon first went to Norfolk when, early in the 1914–18 war, he was put in charge of the surgical division of the Norfolk War Hospital at Thorpe, and in 1919 he was appointed O B E for his surgical work among the casualties from the Western front The same year he was appointed assistant surgeon to the Norfolk and Norwich Hospital, and he was also surgeon in charge of the Ministry of Pensions orthopædic clinics and surgeon to the Ministry's limb-fitting centre at Norwich In the next few years he joined the staffs of other local hospitals, including the Norwich Maternity Hospital, the Patrick Stead Hospital, Halesworth, St Andrew's Hospital, Thorpe, and the Jenny Lind Hospital, Norwich His private practice grew quickly, but he found time to keep up with advances in general medicine, for he was interested not only in surgery He was the first surgeon to use radium at the Norfolk and Norwich Hospital

During the late war he was group adviser to the Norfolk area of the Emergency Medical Service, and in 1943 he was appointed deputy regional adviser in surgery to the Ministry of Health He retired from his hospital appointment in 1955, but he continued to sit as a member of the hospital management committee

A colleague writes

Noon was what we Norfolk people call a *character* I shall never forget him going round the wards with the inevitable bowler on the back of his head, illustrating his observations on the patients from his wealth of aphorisms Nor shall I forget his rare clinical acumen and his ability quickly to size up his patients He had a pungent wit and could be outspoken in committee, and he had strong views on the Welfare State and what he considered bureaucratic medicine At a first meeting his manner might seem abrupt, but those of us who knew him well knew also that nothing would prevent him from obeying any call for help He was a keen and discriminating collector of first editions, old silver, and ivory

Mr Noon married in 1921 Cecily, daughter of Mr F W South She survives him with their son, Mr C F Noon, F R C S

IVY EVELYN HASLAM

M D Lond , M R C P

Dr Haslam, who died on Jan 11 at the age of 79 was the first woman to take the M R C P when, in 1909, women were admitted to the examination

As Ivy Woodward she was educated at Bromley High School, Bedford College, and the London School of Medicine for Women After qualifying in 1903 she held house-appointments at the Royal Free Hospital and at the Belgrave Hospital for Children Later she became assistant to the clinical pathologist, curator of the museum, and demonstrator in morbid histology at the Royal Free She was also clinical assistant at the New Hospital for Women and the Royal Hospital for Diseases of the Chest before she was appointed medical registrar at the Royal Free Hospital In 1908 when she took the M D Lond she qualified for the gold medal

In 1910 she married Dr A C Haslam, who practised at Bromley, Kent After her marriage she gave up regular medical work She had two sons and three daughters (who survive her), and her family became her main concern, but throughout her life she never lost her interest in medicine She also found time for wide cultural interests, especially in literature and language After her husband's death in 1927 she moved to Gerrard's Cross, and to support her growing family she took up infant-welfare and school-inspection work Between 1931 and 1948 she held appointments as medical officer to infant-welfare clinics in Camberwell and Wandsworth In 1948 she retired from all medical work and moved to London

H K W , a fellow student at the Royal Free, writes

Ivy Woodward's charming personality, keen sense of humour, and tolerance of other peoples' point of view made her popular with her colleagues and with her patients As one of the visiting physicians at the Royal Free said, at a time when medical women were not accepted as they are today, " Her kindness and consideration for her patients are remarkable " It was regrettable that after her marriage she was able to do only a limited amount of medical work, a great loss to the profession of one so gifted

ARTHUR HENRY CROOK

M A , M Chir Camb , F R C S

Mr A H Crook, formerly orthopædic surgeon to the Eastbourne group of hospitals, died on Jan 19 at the age of 72 He was born at Southampton in 1884 From Cambridge he obtained an exhibition scholarship to Guy's Hospital After qualifying in 1908 he held house appointments at Guy's, and in 1911 he took the F R C S and in 1912 the M CHIR The same year he settled in practice in Eastbourne, and soon afterwards he was appointed assistant medical officer to the Princess Alice Hospital there During the 1914-18 war he served with the Royal Navy in Antwerp, Gallipoli, when he was mentioned in dispatches, and later on the Somme and in Ireland

On his return to his practice he took up his work at the Princess Alice Hospital, and in 1932 he became surgeon there In 1936 he was due to retire, but the post of fracture surgeon was created for him and he held it till 1951 Up to last year he occasionally acted as a locum In 1933 he helped to found the Eastbourne Sailing Club, and was in turn vice-commodore, commodore, and vice president for life He leaves a widow, three sons, and a daughter

Mr RUFUS THOMAS

C A B writes

In the long struggle over conditions of service of whole time consultants Rufus Thomas took a leading part His long service to the Whole Time Consultants' Association, first as secretary and then as president, was recognised when he was made honorary member of the association He gave evidence before the Royal Commission on Taxation of Profits and Income, and there and elsewhere he always presented his case in clear precise words and in a kindly and persuasive manner

Notes and News

THE REMUNERATION CLAIM

Representatives of the Negotiating Committee are to meet the Minister of Health on the morning of Wednesday, Feb 20 The full committee will meet on the afternoon of that day

WORLD HEALTH ORGANISATION

Poland, Albania, and Bulgaria have informed the Director General that they intend to resume active participation in W H O this year

Dr A T *Shousha, regional director for the Eastern* Mediterranean, will be succeeded on Sept 1 by Dr A H Taba

FAMINE IN IRELAND

The Great Famine of 1845–52 was not the first nor the last period of acute distress in Ireland It has, however left an enduring mark on popular memory because of its duration and severity Memories still linger in Irish oral tradition A new study by a group of specialists in the period [1] contains seven sections, of which that by Sir William MacArthur, dealing with the medical history, may prove the most interesting to medical and other readers

The cause of the famine was a fungus disease of the potato which appeared in the form of black spots on the leaves, with, on the under surface a whitish mould containing the spores These were conveyed to other potato plants by wind and insects particularly when the weather was warm and damp The potato was almost the sole food of about a third of the population, and a main article of diet of a much larger proportion On the heels of each famine there came an epidemic of fevers—mainly typhus and relapsing, both conveyed by the common louse of man On one occasion cholera added to the disaster Well over half a million people died In the better classes relapsing fever was almost unknown, whereas typhus was contracted by many doctors and clergy from their attendance on the sick, and by members of the gentry who were *infected* in crowded assemblies either while presiding as magistrates, sitting on relief committees, attending as jurors, or helping to relieve the overwhelming distress by which they were surrounded One out of every thirteen doctors died at their posts

AUSTRIAN BIOGRAPHIES

Theodor Billroth once wrote to Johannes Brahms "I have never met a great researcher who was not basically an artist of a sort" The truth of this statement is borne out by reading (in German French, or English) the concise biographies of 51 distinguished Austrian doctors that are contained in an interesting book [2] compiled by Professor Schönbauer and Dr Marlene Jantsch The proceeds will be used to provide subventions for scientific publications

---

University of Cambridge

Dr J D Lever, university lecturer in anatomy, has been elected to a staff fellowship at Trinity College on his appointment as college lecturer

Queen's University, Belfast

At the summer graduation Air Marshal Sir James Kilpatrick will receive the honorary degree of LL D in recognition of his services for medicine in the Royal Air Force

University of Birmingham

On Dec 14 the following degrees were conferred

M D—Roy Astley, B D Bower M G Fitzgerald, T A Phillips, Rachel F W Sillett G F Trobridge

M B, Ch B—Margaret J Aldridge G H Berry K G Branch D C Colwell J H Croft, C M David G H Davies Marion K Donovan, A M Evans G S Farmer, I M Fletcher D M Gardiner, N H N Gardner N R Houlston J W E Johnson P W Lee, Barbara S M Marshall D H Tarkett

Mr A L T Easton has been appointed lecturer in obstetrics and gynæcology

Sir Solly Zuckerman F R S, will give the Sir Josiah Mason lectures during the 1957–58 session He is to speak on control of population growth

Royal College of Obstetricians and Gynæcologists

At a meeting of council held on Jan 26, with Sir Charles Read, the president, in the chair, the following were elected to the membership

D C Aird, G B Batchelor, R A T Boland, G D D Cable, Mahomed Ismail Cassimjee, J S W Chambers Probhat Kumar Choudhuri, C A B Clemetson K I *Digwood* Ammud Freier, W J Garrett William Gault, William Gavin, Ivan Goldman C J Goosen, Bernard Kirsch, Margaret A Lakeman E W Little, H H McCrostie, J G Markus, A E B Matthews T T E Michael A B Miller Arun Kumar Mitra, Jessie M B Muirhead A G Muttuthamby, A B L Peake, A C C Pinion L J Rice, Ray Richards T J Ryan, G J W Stump Sarosh Meher Thanevala, K F G Wilson, Robert Yule

North of England Obstetrical and Gynæcological Society

The following officers have been elected for 1957

President Mr F Stabler vice presidents, Dr E A Gerrard, Mr P Malpas, Mr H Agar Mr G R MacDonald Dr W Hunter, hon treasurer, Mr C H Walsh, *hon general secretary*, Mr T J Burk, hon reporting secretary, Miss U M Lister

Royal *College of Physicians of London*

Prof J R Squire will deliver the Oliver Sharpey lectures *on Tuesday and* Thursday, March 12 and 14, on the functions of the plasma proteins Dr L C Hill will give Lumleian lectures on Tuesday *and Thursday, April* 2 and 4, on systemic lupus erythematosus All lectures will be held at 5 P M at the college, Pall Mall East, S W 1

Course on Child and Family Psychiatry

The department of child psychiatry of the Ipswich and East Suffolk Hospital is holding a course on this subject from April 8 *to* 12 The course has been recognised by the Ministry of Education for school medical officers and by the Ministry *of Health* for maternity and child-welfare officers Further particulars may be had from 11, Fore Street, Ipswich

International Congress on Occupational Health

This congress will be held at Helsinki from July 1 to 6 Subjects chosen for discussion at the plenary sessions include industrial noise, evaluation of invalidity, industrial hygiene norms, and human engineering Further particulars may be had from Dr Pertti Sumari, secretary general of the congress, Tyoterveyslaitos, Haartmaninkatu 1, Helsinki, Finland

Preventing Delay of Ambulances

From Feb 1 ambulances bringing emergency cases into Edinburgh from the country are being *met at the outskirts* of the city by a gong fitted escort car or ambulance, manned by a driver who knows the district well, who will lead the incoming ambulance to the hospital by the quietest and quickest route A similar scheme was introduced in Glasgow at the beginning of the year

Visit to Baltic and U S S R

The Society for Cultural Relations with the U S S R hopes to organise for its *medical* section a *Baltic* cruise which will visit Copenhagen, Stockholm, and Helsinki, and spend 6–10 days in Leningrad and Moscow during September *Doctors,* medical students, or members of their families—whether or not they are members of the society—are invited to *apply* for further particulars to the secretary, 14, Kensington Square, London, W 8

Wellcome Trust

The Trust has announced *further* benefactions, amounting *to* £173,500, which bring the total distributed over the past twelve months to £401,500 The latest awards include the following

Up to £35 000 to the University of Edinburgh *for* the cost of *rebuilding animal* houses at the Institute of Animal Genetics

Up to £60 000 to the University of Leeds towards the cost of building research laboratories *for medical physics* and urology on the site of the Leeds General Infirmary

Up to £35 000 to the Royal College of Surgeons of England for the completion of the Wellcome Museums at *the* college

Up to £13 000 to the University of Manchester for the cost of a mobile radiographic and laboratory unit for use primarily in field work on the rheumatic diseases

Up to £15 000 to the University of St Andrews for the cost of adding Wellcome Laboratories of Pharmacology to the Gatty Marine Laboratory

The trustees have agreed, in principle, to present a motor cruiser to the Medical Research *Council* to assist communication between the council's laboratories at Yajara on the Gambia River and the branch laboratory some 70 miles further up the river This vessel would be adaptable as a mobile research laboratory for use in field studies in the interior of the Gambia territory

Fellowship for South African Medical Graduates

The Eli Lilly medical research fellowship ($3000 p a) is open to South African doctors who wish to work in the United States Further details can be had from Dr H A Shapiro, P O Box 1010, Johannesburg, South Africa

International Hospital Federation

This federation is to hold a congress at Lisbon, from June 3 to 7 The main theme will be International Cooperation for Hospital Development—the Hospital of the Future Further particulars may be had from the secretariat of the federation, 10, Old Jewry, London, E C 2

Central Council for Health Education

The council's summer school will be held at Bangor, from Aug 20 to 30 The subject will be the promotion of health and techniques of health education Further details may be had from the medical director of the council, Tavistock House, London, W C 1

Royal Statistical Society

Frances Wood Prize —This prize (50 guineas) is offered for the best investigation, on statistical lines, of a problem which bears directly or indirectly on economic or social conditions Further particulars may be had from the hon secretaries of the society, 21, Bentinck Street, London, W 1 The closing date for submission of essays is Sept 30

International Embryological Conference

This conference, which is sponsored by the *Journal of Embryology and Experimental Morphology*, will be held in the department of anatomy of the University of Cambridge from April 10 to 13 Copies of the programme may be had from Mr D R Newth, PH D , department of zoology, University College, London, W C 1

N H S Superannuation Concession

Medical and dental practitioners and part time specialists in the National Health Service who elected to receive a contribution of 8% of their superannuable remuneration towards payment of premiums on their insurance policies instead of joining the service's superannuation scheme may now be allowed to substitute for the original policies recognised for purposes of the option, annuity policies which would qualify for the new income tax relief afforded under section 22 of the Finance Act, 1956 Recognition of the substituted policies and payment of the Minister's contribution in respect of them will be subject to the following conditions

Where the original policy is made into a paid up policy, that policy shall not be assigned or otherwise surrendered before maturity date A breach of this condition would lead to the discontinuance of the 8% contribution

Where the original policy is surrendered all the money derived therefrom shall be used in the purchase of the substituted policy

Applications for approval to substitute policies should be sent to the Health Services Superannuation Division, Government Buildings, Honeypot Lane, Stanmore, Middlesex

THE DISINTEGRATIVE ACTION OF THE NERVOUS SYSTEM*

William Phillips
M.D., B.Sc. Wales, F.R.C.P.
PHYSICIAN TO THE UNITED CARDIFF HOSPITALS

Sherrington's first masterpiece, his Silliman memorial lectures, was published in 1906 as *The Integrative Action of the Nervous System*. It is therefore the fiftieth anniversary of the publication of a book which will remain a landmark in the history of medicine. 1956 marks also the centenary of the birth of another great neurologist, born only the year before Sherrington, Sigmund Freud, and so I felt it not inappropriate today to discuss a topic which I believe will become of increasing importance as advances in medicine mop up small pockets of resistance in localised fields of pathology.

* * *

That the nervous system itself might be a source of disease is no new idea, and as far back as 1868 William Gull said "there is a neuropathology from the brain", but in this and in many other ways that remarkable clinician was much ahead of thought in his day. Since Gull's time, many have expressed the same sort of view and none in more intriguing a fashion than did Wilfred Trotter (1941) in his essay on the Insulation of the Nervous System, where he reflects that

> "It may be worth suggesting, however, that the problem (the reason for the curious embryology of the nervous system) has also a functional side and that the epiblastic origin of an organ that is ultimately to be deeply embedded in mesoblastic tissues possibly has the function of contributing its strangeness and therefore its effectiveness, to the nervous system as a whole. This quasi-hostility between neural and somatic, between brain and body, is a suggestive and perhaps a disturbing thought."

Morley Roberts (1926) in his *Malignancy and Evolution* said "the body is composed of differentiated cell colonies living in a state of hostile symbiosis in precarious and uneasy balance so that balance between organs and tissues may be easily lost—the brain is a morbid overgrowth and tumour its tremendous size may not only be one of the causes of malignancy but ultimately the cause of extermination of the human race." But this was based on philosophic speculation and somewhat strained analogy, however disturbingly the last clause may read today.

Even when the initial novelty of seeking out psychosomatic relationships had been overcome, those interested particularly in this subject were slow to investigate such possibilities except where mechanisms capable of producing local changes seemed likely, from their knowledge of physiology, to be possible and an analysis (Engel 1954) of the first fifteen volumes of the journal *Psychosomatic Medicine* showed that 80% of the 206 articles were devoted to the circulatory system, skin, gastro-intestinal tract, respiratory system, pain, and metabolic disturbances. I wonder how many of our teaching hospitals and great special hospitals could with all the good will in the world derive from their existing case-notes material of real value to a serious student of such matters. I would not myself be optimistic in this regard. What indeed can one expect in the way of appreciation of the patient as a person, of his hopes and fears, aims and beliefs, when one encounters a rugged patient introduced by a highly trained senior registrar as an interesting example of disseminated sclerosis commencing at 59 and finds that the description "porter" on his case-notes had been of so little interest, and resulted in so little inquiry, that the vision of a man balancing a hundredweight of baskets in a tall chimney on his head for the working hours of upwards of forty years had quite escaped comment?

* * *

While the endocrine glands are subject to most of the ordinary pathological changes—for example, tuberculosis and neoplasm—one of the striking features of the common endocrine disorders is the remarkable circumstance that disorder or atrophy is the main feature of their pathology. I find it difficult from clinical experience to accept the view that conditions such as thyrotoxicosis, myxœdema and many of the disorders of menstruation, diabetes mellitus, and the like, often commence in a localised disturbance in the glands concerned, without preceding central disorder, and it would be my conviction that emotional disturbances are the main, if not for practical purposes the sole, origin of such central derangement.

In two such different conditions as rheumatoid arthritis and diabetes mellitus there is much to compare. Of the first, Bauer (1956) has said from an experience of 300 patients studied over twenty-five years, that "no significant lead had emerged as to cause or cure—an impasse which faced all investigators of the disease." I think the walls of our college will approve his conclusion that "rest emerged as the keystone of treatment, and the definite natural tendency for the disease to remit cast doubts on the many reported 'cures'." An immediate analogy can be drawn between a chronic relapsing joint condition, which is in some sense modified by adrenocorticotrophic hormone or cortisone, and the state of the diabetic patient controlled by insulin. I regard the insulin treatment of diabetes as the most perfect example of how scientific medicine has succeeded in blinding itself to the existence of the patient while at the same time boasting of his survival. To most treatment of diabetes is treatment of a blood chemistry unrelated to treatment of a person except in so far as he is expected to fall in with quite rigid authoritarian dictates as to his food and other habits for the rest of his life—all of course with most kindly intentions. Yet, consideration of experimental evidence might long ago have introduced an element of caution into this outlook. I have elsewhere summarised (Phillips 1953a) the experimental pointers to objections to the concept of diabetes as a simple endocrine lack from disease of special tissues in the pancreas.

Concerning the possibility that emotional factors may be responsible for diabetes there is, of course, much literature, some of it critical and suggestive (Daniels 1948). I have encountered four patients with severe diabetes where the experimental situation seems in part paralleled—four patients in whom an abrupt onset followed periods of intense emotional stress and in whom by good fortune prompt diagnosis was possible by reason of the nature of the presenting symptoms. In all immediate high insulin dosage was used and efforts were made to deal with the psychological situation. After progressive diminution in their insulin requirements, all in the course of four to eight weeks became free from glycosuria without insulin, and they have remained so on ordinary diets, living ordinary lives since; two of them I judged to have made an emotional adjustment more from developed traits in their own make-up than by my help. I think the reason why I have only four such patients is that until recent years I had not recognised the implications of the response of the first patient, whom I saw in a military hospital. Now, were I seeing many diabetic patients, I should be increasingly interested in what is going on in the patients'

---

* From the Bradshaw lecture for 1956, delivered to the Royal College of Physicians of London on Nov. 8.

6963

lives and minds There are evidently further analogies in thyrotoxic glycosuria

* * *

The *study of peptic ulcer*—a disorder which because a pain or other symptom causes the patient usually to be aware of variations in his state quite quickly—is of great value in teaching the doctor the importance of body-mind relationship The correlation of its important complications with acute periods of stress is frequent, although it by no means follows that the essential information is available to any clumsy, untutored approach Success often seems to attend competent surgical treatment of the patients whose ulcers are bothering them mainly because of the effects of the fibrosis of healing, but in this extraordinarily important disorder the evaluation of therapy must surely be long-term

Browning and Houseworth (1953) interested themselves in the development of new symptoms following medical and surgical treatment of duodenal ulcer They noted a significant decrease in ulcer symptoms following gastrectomy but also a parallel increase in other illness, whereas in the medically treated patients, who were often incompletely relieved of their ulcer symptoms, there was no redistribution of symptoms The most important point which emerged from their study was that the longer the period of follow-up, the more significant the differences in the two groups appeared The earlier a physician with the interest and skill necessary to recognise the nature of the causative stress can help to secure graceful adjustment to the general life situation, the more the gross permanent effects of ulcer scarring can be prevented or minimised

Grace (1953) and his co-workers studied patients with duodenal ulcer to estimate the significance of this kind of statement, using two groups matched for stage in the disease and in many other ways, and found that, of the patients they had treated without using dietetic measures or new or old antispasmodics, about two thirds after three years showed X-ray evidence of complete healing, whereas, of the comparable patients treated in other clinics with conventional drug and dietetic treatment only one-third were similarly healed The evidential basis for accepting a stress causation of peptic ulcer so amply demonstrated in the studies by Stewart Wolf (1949) on patients with gastric fistulæ, will be well known to you, of it, Wolf has said

> "Among stimuli sustaining gastric hyperfunction, troublesome life situations were found to be prominent and surprisingly potent, often outweighing the effects of powerful pharmacodynamic agents In treatment of duodenal ulcer, getting to know the patient and offering him help and encouragement in dealing with his day-to day challenges and problems appear to offer more than do diets and antacids alone"

The varying course of illnesses such as thyrotoxicosis and ulcerative colitis—both again amenable in different ways to medical and surgical approaches in therapy—parallel with extraordinary precision the natural history of peptic ulceration, and in these conditions I think that the onset, rate of improvement, and relapses during treatment, are conditioned by stress exclusively

* * *

I would like now to touch on a concept which seems possibly important Whether genetic or other constitutional factors are essential before the mind can produce somatic damage is unlikely to be determined at all easily, and it *does not* really *matter* in this discussion whether the amount of added stress necessary to produce somatic changes in an individual has to be little or great It is in quite another direction that the practical importance of the situation lies I put forward the proposition that in some patients the life situation is incompatible with his personality in such degree that unaided he can make no adjustment, in others, partial adjustment is possible, while in a third group adjustment is more or less readily achieved I suspect that conditions such as some psychoses may come into the first group, and likewise many examples of ulcerative colitis, while others are at the more severe end of the second group. Possibly again in the first group, or in the more severe part of the second, illnesses such as disseminated scleros may need to be placed In the more benign part of the middle group, and perhaps in *all* parts of the third group, come the peptic ulcerations, asthma, thyrotoxicosis and diabetes, while migraine, for example, and psoriasis will most often be in the first group I am satisfied that in the whole of the third group, and in very much of the second group, already enormously rewarding therapeutic opportunities are ignored by preoccupation with local lesions and peripheral ideas of ætiology My conviction would be that with sufficient skill in investigation, many, if not most, of the first group will also become amenable to non-mechanistic approach in treatment

* * *

One of the most disturbing features of the failure of modern medicine, especially academic medicine, to face up to the implication of Freud's major discovery is the extraordinary ignorance one finds of what he actually thought and said There can be little excuse for ignorance of his life now that the brilliant and devoted biographical study by Ernest Jones—soon, I hope, to be completed—has appeared Were Freud's works not available in the happiest of English translations, one could excuse more readily ignorance of them, and I find it odd, for example, that few seem to have noticed that the fourteenth edition of the *Encyclopædia Britannica* (1929) contains a most precise article on psycho analysis by Freud himself His account of the subject matter of psycho analysis is an extremely succinct and important one Now, over thirty years later, much could be said of the validity of the details of his exposition, but it is certain that in the history of medicine his name will live as long as that of any of the mighty originals we honour That the theory of psychology and the rigid system of treatment he built up are both unlikely to survive unaltered does not detract from his greatness, and, at this distance, they can be seen as the inevitable effects of the cultural atmosphere of the times and places in which he spent his formative years

* * *

Prejudice and bias aside, two important kinds of difficulty prevent easy recognition of the effects of emotion on the tissues On the one hand, the causative disturbance may be unrecognisable except by the trained observer, or, though less subtle, may still be beneath consciousness, or on the *other hand* there may be *no* symptoms to attract the patient's notice Between these difficulties come those disorders which, though apparent enough, do not make the patient think of an emotional origin—simply because the time-relationship is not impressed on him either by previous experience or by immediacy of effect

I have said elsewhere (1953b) that for *most people* the state of health is not a very conscious matter unless sharp deviations from the customary state take place, and many will fail to recognise those differences of personality which to others are their distinguishing marks To feel well in the conventional sense is an *exaggeration*, when well one feels nothing of one's health unless in response to external stimulus In many circumstances, quite gross changes of mental comfort can occur without the patient considering even the possibility that his reaction has been other than ordinary If long experience has brought home to him that his usual response to worry or upset has been, say, abdominal discomfort, diarrhœa, frequency of micturition, or headache, then an unusual severity of such symptoms may make him aware that a particularly severe stress has been responsible, but even so apparently simple a correlation is by no means usual—and in the definition of stress it is prudent to remember Plutarch's remark that it is "man's nature to resent evil words more than evil deeds, for it is more easy to submit to injury than insult"—and in considering response to stress, to recall Shakespeare's famous lines "Give sorrow words, the grief that does not speak whispers the o'er fraught heart, and bids it break."

* * *

An almost insuperable difficulty arises where a response is bizarre, and I shall illustrate this by a few words on multiple lipomatosis. The ætiology of this curious disorder has been little discussed, though Heilmann and Sonneck (1953), describing a case in which the lipomatosis seemed to follow electric shock, refer to others attributed to head injury, particularly injury to the base of the skull.

When I first saw the condition twenty-five years ago, even the patient's subsequent suicide did not make me reflect on why he had developed an enormous number of lipomata. Early in the war, I saw a second patient who in six weeks had developed numerous lipomata about the arms, thighs, and trunk. There were so many large ones in the forearms that, when he presented arms, a tourniquet effect made him relax his grip quite quickly, and on two such occasions his rifle clattered to the ground. He presented an antecedent intense anxiety state based on readily understandable factors, and when we had relieved his emotional disorder he reminded us that no further lipomata had appeared, but again I thought little of the matter. On returning to civil life, I was almost at once presented with a third problem of this kind—the combination of an intense exhaustion and anxiety state in an exceedingly active and responsible young man with gross lipomatosis of acute onset, mainly affecting the arms. Twenty-nine lipomata were neatly excised while he was having a short course of modified prolonged narcosis, and I was greatly intrigued to find that, with the relief of his psychogenic disorder, no further lipomata appeared. I waited with some eagerness for another comparable patient, and within the last fortnight I have seen one. Unfortunately it is some seven years since his lipomata appeared, so that critical study of the life situation at the relevant time will be difficult, but it is clear that in this instance a man of 63 developed the condition in circumstances which caused him soon afterwards to retire prematurely from his occupation. Tentative exploration of the last patient has not gone further, but I would suggest that this slight personal experience of four patients with multiple lipomatosis cannot be dismissed as irrelevant to my main theme. I would agree at once that the development of benign fatty tumours seems a very odd way for the body to express its discontent, but if these observations have substance, then I would suggest that there is no tissue in the body which may not react in a similar way.

The effect of stress on body resistance to infection is difficult to define although one suspects some close connection when one encounters, for example, a patient who has had pneumonia several times in thirty years, always immediately after severe stresses. *Recurrent* herpes, simplex and zoster, in my small experience, has always been so correlated, and this view is shared by others (Weichselbaum 1956). When one feels that a real improvement has taken place in a patient's personal adjustment to life it is intriguing to hear comments such as "It's odd I haven't had another attack because, if this had happened to me before treatment I'm certain I would have had a very bad attack—I suppose it's because I had begun to feel happier and easier." This remark was made by an intelligent patient who had failed to show her expected somatic reaction when her daughter was killed tragically the day after what was to have been a final discussion of her health.

There are those who insist that patients with disseminated sclerosis are apt to show a uniform type of personality. My co-editor, Hugh Garland, for example, writes:

> "early examples of disseminated sclerosis, when there can be little possibility of personality changes having arisen through gross disease of the brain, show many striking features. Usually physically attractive, these people are almost invariably polite, quiet, pleasant and devoid of aggressive talk or behaviour, they dislike quarrels or arguments, or any show or display of temper. In the author's view it is this type of person, and probably only this type, which develops disseminated sclerosis, and in such people it is very commonly the fact that prior to the onset of the first symptoms, there has been clear evidence of emotional stress. It may well be that trauma, parturition and the other factors mentioned above operate by some similar mechanism." (Garland 1953.)

When one considers the difference in the possibility of regeneration in damaged nervous tissue as compared with tissues where normally mitosis is active and replacement constant and frequent (Leblond and Walker 1956), it seems clear that, if stress damage arises in the nervous system, the only recovery to be expected is the removal of the effects of immediate neuroglial or similar reaction. Schwab and Prichard (1950) studying a hundred parkinsonian patients with special interest in psychosomatic effects in stable, vulnerable, and difficult personalities concluded that there is a close correlation between personality and the effects of environmental stress. They found that, while all patients were temporarily worse with short-lived stress, only 12% of the 42 patients in the stable group showed permanent aggravation of their disorder when exposed to long-continued or severe stress, whereas 33 (27%) of the vulnerable and 25 (56%) of the difficult-personality groups were so affected. Others have suggested that some patients with parkinsonism may be showing reaction to stress in the very centre of the integrating mechanism, and many examples of chronological correlation between exacerbations and stress are on record. Again, I had never considered this possibility until quite recently when I was a little chagrined by a patient's unprompted and quite categorical account of her correlation not only of an exacerbation in the parkinsonism but also of its origin with clear-cut episodes of severe stress.

The more one studies such matters, the more one realises how extraordinarily blind our preconceptions make us. We tend to see only what we expect to see, and it is hardly surprising that many can practice over a long period of years without ever realising that mental factors can induce a physical disease. Particularly is this understandable when one considers how very much more careful and understanding an approach is required to elicit this type of history. We may recall what Oliver Wendell Holmes said in 1883 about the futility of much of medical practice:

> 'many a suicide would have been prevented if the doctor's wife had visited the victim the day before it happened. She would have seen in the merchant's face his impending bankruptcy while her stupid husband was prescribing for his dyspepsia and indorsing his note; she would recognize the love lorn maiden by an ill adjusted ribbon—a line in the features—a droop in the attitude, a tone in the voice—which mean nothing to him, and so the brook must be dragged tomorrow.'

It cannot be said too often that when one is studying the possibilities of psychosomatic ætiology to ask a patient whether anything may be worrying him is a waste of

lives and minds There are evidently further analogies in thyrotoxic glycosuria

* * *

The study of peptic ulcer—a disorder which because a pain or other symptom causes the patient usually to be aware of variations in his state quite quickly—is of great value in teaching the doctor the importance of body-mind relationship The correlation of its important complications with acute periods of stress is frequent, although it by no means follows that the essential information is available to any clumsy, untutored approach Success often seems to attend competent surgical treatment of the patients whose ulcers are bothering them mainly because of the effects of the fibrosis of healing, but in this extraordinarily important disorder the evaluation of therapy must surely be long-term

Browning and Houseworth (1953) interested themselves in the development of new symptoms following medical and surgical treatment of duodenal ulcer They noted a significant decrease in ulcer symptoms *following gastrectomy but also a parallel increase in* other illness, whereas in the medically treated patients, who were often incompletely relieved of their ulcer symptoms, there was no redistribution of symptoms The most important point which emerged from their study was that the longer the period of follow-up, the more significant the differences in the two groups appeared The earlier a physician with the interest and skill necessary to recognise the nature of the causative stress can help to secure graceful adjustment to the general life situation, the more the gross permanent effects of ulcer scarring can be prevented or minimised

Grace (1953) and his co-workers studied patients with duodenal ulcer to estimate the significance of this kind of statement, using two groups matched for stage in the disease and in many other ways, and found that, of the patients they had treated without using dietetic measures or new or old antispasmodics, about two-thirds after three years showed X-ray evidence of complete healing, whereas, of the comparable patients treated in other clinics with conventional drug and dietetic treatment only one-third were similarly healed The evidential basis for accepting a stress causation of peptic ulcer so amply demonstrated in the studies by Stewart Wolf (1949) on patients with gastric fistulæ, will be well known to you , of it, Wolf has said

> " Among stimuli sustaining gastric hyperfunction, troublesome life situations were found to be prominent and surprisingly potent, often outweighing the effects of powerful pharmacodynamic agents In treatment of duodenal ulcer, getting to know the patient and offering him help and encouragement in dealing with his day to day challenges and problems appear to offer more than do diets and antacids alone "

The varying course of illnesses such as thyrotoxicosis and ulcerative colitis—both again amenable in different ways to medical and surgical approaches in therapy—parallel with extraordinary precision the natural history of peptic ulceration, and in these conditions I think that the onset, rate of improvement, and relapses during treatment, are conditioned by stress exclusively

* * *

I would like now to touch on a concept which seems possibly important Whether genetic or other constitutional factors are essential before the mind can produce somatic damage is unlikely to be determined at all easily, and it does not really matter in this discussion whether the amount of added stress necessary to produce somatic changes in an individual has to be little or great It is in quite another direction that the practical importance of the situation lies I put forward the proposition that in some patients the life situation is incompatible with his personality in such degree that unaided he can make no adjustment , in others, partial adjustment is possible , while in a third group adjustment is more or less readily achieved I suspect that conditions such as some psychoses may come *into* the first group, and likewise many examples of ulcerative colitis, while others are at the more severe end of the second group Possibly again in the first group, or in the more severe part of the second, illnesses such as disseminated sclerosis may need to be placed In the more benign part of the middle group, and perhaps in all parts of the third group, come the peptic ulcerations, asthma, thyrotoxicosis and diabetes, while migraine, for example, and psoriasis will most often be in the first group I am satisfied that in the whole of the third group, and in very much of the second group, already enormously rewarding therapeutic opportunities are ignored by preoccupation with local lesions and peripheral ideas of ætiology My conviction would be that with sufficient skill in investigation, many, if not most, of the first group will also become amenable to non-mechanistic approach in treatment

* * *

One of the most disturbing features of the failure of modern medicine, especially academic medicine, to face up to the implication of Freud's major discovery is the extraordinary ignorance one finds of what he actually thought and said There can be little excuse for ignorance of his life now that the brilliant and devoted biographical study by Ernest Jones—soon, I hope, to be completed—has appeared Were Freud's works not available in the happiest of English translations, one could excuse more readily ignorance of them , and I find it odd, for example, that few seem to have noticed that the fourteenth edition of the *Encyclopædia Britannica* (1929) contains a most precise article on psycho analysis by Freud himself His account of the subject matter of psycho analysis is an extremely succinct and important one Now, over thirty years later, much could be said of the validity of the details of his exposition, but it is certain that in the history of medicine his name will live as long as that of any of the mighty originals we honour That the theory of psychology and the rigid system of treatment he built up are both unlikely to survive unaltered does not detract from his greatness, and, at this distance, they can be seen as the inevitable effects of the cultural atmosphere of the times and places in which he spent his formative years

* * *

Prejudice *and* bias aside, *two* important kinds of difficulty prevent easy recognition of the effects of emotion on the tissues On the one hand, the causative disturbance may be unrecognisable except by the trained observer, or, though less subtle, may still be beneath consciousness , or on the other hand there *may* be no symptoms to *attract* the patient's notice Between these difficulties come those disorders which, though apparent enough, do not make the patient *think* of an emotional origin—simply because the time-relationship is not impressed on him either by previous experience or by immediacy of effect

I have said elsewhere (1953b) that for most people the state of health is not a very conscious matter unless sharp deviations from the customary state take place, and many will fail to recognise those differences *of personality* which to others are their distinguishing marks To feel well in the conventional sense is an exaggeration , when well one feels nothing of one's health unless in response to external stimulus In many circumstances, quite gross changes of mental comfort can occur without the patient considering even the possibility that his reaction has been other than ordinary If long experience has brought home to him that his usual response to worry or upset has been, say, abdominal discomfort, diarrhœa, frequency of micturition, or headache, then an unusual severity of such symptoms may make him aware that a particularly severe stress has been responsible, but even so apparently simple a correlation is by no means usual—and in the definition of stress it is prudent to remember Plutarch's remark that it is " man's nature to resent evil words more than evil deeds , for it is more easy to submit to injury than insult "—and in considering response to stress, to recall Shakespeare's famous lines " Give sorrow words , the grief that does not speak whispers the o'er fraught heart, and bids it break "

lives and minds There are evidently further analogies in thyrotoxic glycosuria

The study of peptic ulcer—a disorder which because a pain or other symptom causes the patient usually to be aware of variations in his state quite quickly—is of great value in teaching the doctor the importance of body-mind relationship The correlation of its important complications with acute periods of stress is frequent, although it by no means follows that the essential information is available to any clumsy, untutored approach Success often seems to attend competent surgical treatment of the patients whose ulcers are bothering them mainly because of the effects of the fibrosis of healing, but in this extraordinarily important disorder the evaluation of therapy must surely be long-term

Browning and Houseworth (1953) interested themselves in the development of new symptoms following medical and surgical treatment of duodenal ulcer They noted a significant decrease in ulcer symptoms following gastrectomy but also a parallel increase in other illness, whereas in the medically treated patients, who were often incompletely relieved of their ulcer symptoms, there was *no* redistribution of symptoms The most important point which emerged from their study was that the longer the period of follow-up, the more significant the differences in the two groups appeared The earlier a physician with the interest and skill necessary to recognise the nature of the causative stress can help to secure graceful adjustment to the general life situation, the more the gross permanent effects of ulcer scarring can be prevented or minimised

Grace (1953) and his co workers studied patients with duodenal ulcer to estimate the significance of this kind of statement, using two groups matched for stage in the disease and in many other ways, and found that, of the patients they had treated without using dietetic measures or new or old antispasmodics, about two-thirds after three years showed X-ray evidence of complete healing, whereas, of the comparable patients treated in other clinics with conventional drug and dietetic treatment only one-third were similarly healed The evidential basis for accepting a stress causation of peptic ulcer so amply demonstrated in the studies by Stewart Wolf (1949) on patients with gastric fistulæ, will be well known to you , of it, Wolf has said

> " Among stimuli sustaining gastric hyperfunction, troublesome life situations were found to be prominent and surprisingly potent, often outweighing the effects of powerful pharmacodynamic agents In treatment of duodenal ulcer, getting to know the patient and offering him help and encouragement in dealing with his day to day challenges and problems appear to offer more than do diets and antacids alone "

The varying course of illnesses such as thyrotoxicosis and ulcerative colitis—both again amenable in different ways to medical and surgical approaches in therapy—parallel with extraordinary precision the natural history of peptic ulceration, and in these conditions I think that the onset, rate of improvement, and relapses during treatment, are conditioned by stress exclusively

I would like now to touch on a concept which seems possibly important Whether genetic or other constitutional factors are essential before the mind can produce somatic damage is unlikely to be determined at all easily, and it does not really matter in this discussion whether the amount of added stress necessary to produce somatic changes in an individual has to be little or great It is in quite another direction that the practical importance of the situation lies I put forward the proposition that in some patients the life situation is incompatible with his personality in such degree that unaided he can make no adjustment , in others, partial adjustment is possible , while in a third group adjustment is more or less readily achieved I suspect that conditions such as some psychoses may come into the first group, and likewise many examples of ulcerative colitis, while others are at the more severe end of the second group. Possibly again in the first group, or in the more severe part of the second, illnesses such as disseminated sclero may need to be placed In the more benign part of the middle group, and perhaps in all parts of the third group, come the peptic ulcerations, asthma, thyrotoxico and diabetes, while migraine, for example, and psoria will most often be in the first group I am satisfied that in the whole of the third group, and in very much of the second group, already enormously rewarding therapeutic opportunities are ignored by preoccupation with local lesions and peripheral ideas of ætiology My conviction would be that with sufficient skill in investigation, many, if not most, of the first group will also become amenable to non-mechanistic approach in treatment
